PREFACE TO FIRST EDITION.

IN the following pages I purpose to confine myself to a description of the Photographic processes on Paper and Glass, as being the two modes of fixing the luminous image that present the most difficulties to the beginner, and, moreover, are those which at the present time are occupying to the greatest extent the attention of the Photographic world.

Almost every one who has commenced this beautiful and fascinating art, has felt the want, to a greater or less extent, of some work which shall contain such simple and definite instructions as will enable him to succeed in the particular processes in which he may be engaged. It will therefore be my endeavour to transcribe to these pages the results of actual experiment, and to lay down those rules for the practice of the various processes which experience has shown to be attended with most success.

In carrying out this design, many variations in the processes will necessarily be omitted; but this will be found a convenience rather than the reverse, to the beginner, as it is a generally admitted fact, that those Photographers who are content to follow some good process to the exclusion of others that have been but imperfectly tried, produce by far the best pictures with the least expenditure of time and trouble.

CHARLES A. LONG.

July, 1854.

PREFACE TO FOURTH EDITION.

A FOURTH edition of "Practical Photography" being called for so rapidly after the issue of the last, confirms my anticipation of the usefulness of a treatise for the instruction of Amateurs and Photographers, in which simplicity of detail, and absence of technicality from the description of the processes, formed the basis of its structure. In the present edition many parts have been entirely re-written, and a paper added on the coloring of positive photographs. The whole has been carefully revised in order to bring the information contained in the various sections down to the present time, a course which I trust will ensure even a larger circulation than has been accorded to the three previous editions.

CHARLES A. LONG.

Bayswater, Oct., 1858.

THE DARK ROOM.

THE room in which the various operations in the Photographic processes about to be described are conducted, should be so constructed that every ray of light can, if necessary, be shut out, especial care being bestowed on the exclusion of that element under and around the door: it is better if there be only one window, near which may be placed the operating table. The light from the window must be modified by placing before it a triple thickness of yellow calico; the light which enters through this screen will not affect the sensitive surfaces, but will enable the operator to conduct the process with ease and comfort. Should a window not be at command, the light of a lamp, surrounded with ruby or yellow glass, can be used with advantage. (*Figs. 1 & 2.*)

Fig. 1.

Fig. 2.

It will be found convenient when using the paper process to have a broad shelf fitted up to hold three or four washing pans; this will answer well at the same time for pinning the paper to while drying. A small shelf near the table will also be a convenience as a resting-place for the bottles containing the chemicals; this enables the table to be kept quite clear and fit for action, which will be found a great

advantage, and will tend much to the success of the various processes.

A pan of clean water and some clean cloths may be advantageously placed near at hand, as likewise vessels for the refuse waters and liquids used in the production of pictures.

The cloths and leathers used in the Collodion process ought to be hung on separate hooks, so as to be kept quite distinct and within reach, and each one should be returned to its place when done with.

The solutions in all the processes require frequently to be filtered; and it may be of service to the novice to describe the way of folding the bibulous paper to be used in the operation. Cut a circle of the paper of twice the diameter of the funnel to be used, and first fold it in half and then in quarter; it will now be found to fit the funnel exactly. The paper is folded in precisely the same way when used with the filter ring.

These remarks will no doubt appear quite unnecessary to many Photographers, now adepts in the art, but I would merely remind them that it has been by attention to minute and apparently trivial matters that they have attained their present proficiency.

THE PHOTOGRAPHIC PROCESSES.

Before entering upon the details of the Photographic processes, it may not be out of place to give some account of the chemical substances used in Photography, and also to make a few observations on their behaviour under certain conditions.

The following list contains the usual chemical preparations concerned in the formation of the Photographic image:

Iodide of potassium.

Nitrate of silver.

Gallic acid.

Pyrogallic acid.

Acetic acid.

Proto-sulphate of iron.

Hypo-sulphite of soda.

To commence then with IODIDE OF POTASSIUM. This salt, consisting of iodine combined with the metal potassium, is formed by saturating a hot solution of pure potassa with iodine, which gives rise to iodide of potassium and iodate of potash. This is evaporated to dryness and exposed to a gentle red heat in a platinum crucible in order to decompose the iodate. The fused mass is then dissolved in water and crystallized.

The photographer should be particularly careful in the purchase of this salt, as it is frequently contaminated with various impurities which render it perfectly useless in Photography. The most usual contaminations are chloride of potassium, and carbonate and sulphate of potassa, either of which would have an injurious effect on its qualities.

Pure iodide of potassium is in crystals of the cubic form, white and opaque, that do not deliquesce in a moderately dry atmosphere, and are perfectly soluble in absolute alcohol.

NITRATE OF SILVER is formed by dissolving pure silver in nitric acid diluted with three times its bulk of water: the solution is evaporated, and crystals of nitrate of silver are deposited in the form of transparent tables on the cooling of the liquid. These are dissolved in water and again crystallized, in order to free them from any adhering nitric acid.

Nitrate of silver is met with in commerce in two states, one in the form of crystals, as just described, and the other in small cylindrical sticks; these latter should be rejected by the photographer, as containing many impurities and contaminations which are not found in the crystallized article. This remark, however, does not apply to the fused nitrate of silver prepared expressly for Photographic purposes. This article is absolutely pure, and is sold in cakes, and not in sticks, as is the common lunar caustic. The foreign matters found in the nitrate of silver of commerce are lead, copper, and potash, each in the state of nitrate. The whole of these impurities are detrimental to the proper action of the nitrate of silver in the various Photographic processes.

GALLIC ACID.—If powdered Aleppo galls be mixed with water to

the consistency of a thin paste, and exposed to the action of the atmosphere at a temperature of 65° for a period of four or five weeks, the evaporation being neutralized by the addition of small quantities of water, they will become mouldy: the liquid is then pressed out and the residue boiled in water. The resulting hot solution must now be filtered, and as it cools will deposit beautiful crystals of gallic acid these are to be boiled in water with some animal charcoal, and the solution again filtered, when on cooling the gallic acid will crystallize in the form of slender needles, having a silky lustre. The gallic acid should be of a light yellow colour, and perfectly free from dark portions; and when dissolved should make a bright and clear solution. 1 oz. of water will dissolve about 4 grs. of gallic acid at the temperature of 60° .

PYROGALLIC ACID.—This beautiful substance is obtained by submitting gallic acid in suitable apparatus to a temperature of 430° Fah., when pyrogallie acid in the form of bright shining scales sublimes and is condensed in the upper part of the vessel. The scales ought to be quite white and free from any tinge of brown, otherwise we may conclude that they have become contaminated with an empyreumatic oil, and that the temperature at which they had been formed was too high.

The only other impurity likely to be discovered in pyrogallie acid is metagallic acid, which is produced from the same cause as the oil mentioned above. The first impurity causes the pyrogallie acid, when mixed ready for developing the picture, to decompose more readily; and the second, if not carefully separated by filtration, causes innumerable blemishes on the surface of the plate.

ACETIC ACID (glacial) is the result of the decomposition of acetate of soda, which has been thoroughly purified by repeated crystallizations, by sulphuric acid; the acetic acid distilling over at a temperature of 125° . The first product is then re-distilled over some dry acetate of soda, and the product submitted to the action of cold until it assumes the solid form; the liquid is then drained from the crystals, which are pure hydrated acetic acid.

There are various impurities in the ordinary strong acetic acid,

such as sulphuric, tartaric, oxalic, and hydrochloric acids; but if the article be carefully prepared, we need not be apprehensive of any contamination. It is above all things necessary that the acetic acid should be of good quality, as so much of the brilliancy and clearness of the pictures produced with it depends on its purity and strength. For the paper processes the operator should reject any sample of acetic acid that does not assume the solid form at a temperature of 50° Fah.

PROTO-SULPHATE OF IRON.—This salt is obtained by treating metallic iron with dilute sulphuric acid, the liquid on evaporation yielding crystals of a bluish-green colour, which after being dissolved and re-crystallized form the pure proto-sulphate of iron. The only impurity of consequence in this salt is due to the peroxidation of part of the base; this, however, may be easily detected by the crystals becoming slightly tinged with yellow. Any indication of the kind in a sample ought to be sufficient grounds for its rejection by the photographer. Should it, however, be inconvenient to procure another sample, the discoloured crystals may be treated with dilute sulphuric acid, washed and dried; they will then be fit for use in making the developing solution.

HYP0-SULPHITE OF SODA.—There are various ways in which this salt can be made; the following appears to be the most simple:—

Mix 1 lb. of finely pulverized calcined carbonate of soda with 10 ozs. of flowers of sulphur; heat the mixture slowly till the sulphur melts; stir the fused mass so as to expose all its parts freely to the atmosphere; then dissolve in water, filter the solution, and boil it immediately with flowers of sulphur. On cooling, after being filtered, it will deposit beautiful crystals of the hypo-sulphite of soda. The impurities likely to interfere with the photographic use of hypo-sulphite of soda are sulphate of soda and carbonate of soda; the former may be detected by the crystals looking dry instead of slightly damp, and the latter by the addition to a solution of the suspected sample of a few drops of sulphuric acid, when effervescence will ensue if carbonate of soda be present. A sample containing carbonate must on no account be used for making a toning bath.

From the foregoing remarks it will be seen how necessary it is to be careful in the selection of the chemicals we are about to use; and I venture to assert that more failures have arisen from inattention to this particular than from any other cause.

THE COLLODION PROCESS.

IN the year 1851 Mr. Scott Archer made known to the world a process by which he had succeeded in taking impressions in the Camera on a film of collodion spread upon a plate of glass.

His process varied very little from that now most recommended, except in a few particulars of manipulation, which practice has shown to be essential to success.

The advantages of such a process had been long admitted, but up to this point nothing of great service had been proposed, except that on albumenized glass, which, from the slowness of its action, was useless for portraiture, and almost so for many other purposes.

The transparency of glass plates, and the film of collodion, as compared with the uneven texture of paper, is a strong argument in its favour; but when we superadd the extreme sensitiveness of the collodion plate, and the ease in the manipulation, nothing more can be desired for obtaining perfect representations of natural objects.

The apparatus required for the Collodion process is of a very simple kind, and consists of the subjoined articles:—

Gutta-percha or glass bath, for holding the nitrate of silver.

The dipper, which consists of a strip of flat glass, having a small support cemented at one extremity for the purpose of holding the glass plate while it is being plunged into the bath.

Levelling stand, with proper adjusting screws for supporting the plate, while the picture is being either developed or fixed.

2 ounce measure.

1 ounce ditto, for developing solution.

Small spouted cup, for hypo-sulphite of soda.

Funnel, and filter-ring; the former for the filtration of the bath,

the latter for the purpose of filtering small quantities of developing solution before use.

Porcelain pan, to hold the levelling stand in order to catch the superfluous liquid.

COLLODION is a solution of gun-cotton, or more properly pyroxyline, in sulphuric æther, and the qualities that fit it for Photographic purposes are, capability of being rendered extremely sensitive to light, toughness, tenacity, and freedom from impurities of any kind.

These objects will be attained by following the method we are about to describe in all its details, the principal points requiring attention being the strength of the acids and the space of time the cotton is exposed to the action of them. The mode of proceeding is as follows :—

Take 12 ounces of nitric acid of the specific gravity of 1360, throw it into a large wedgewood mortar, previously placed under a chimney, or out in the open air; then add 18 ounces of sulphuric acid of the specific gravity of 1840, thoroughly mix them and allow the mixture to cool to 140° Fah.; then immerse finely carded cotton, in small portions at a time, until the acids will just cover the quantity; stir the cotton with stout glass rods in such a manner that it may become perfectly saturated with the acids and that every fibre may be brought under their influence. Some difficulty will be experienced at first to do this properly; but, by attention to the manner of adding the portions of cotton, and care in preventing any air from being carried into the acid mixture entangled in the interstices of the cotton, will soon lead to successful results. If any air is carried down into the acids, it will give rise to the formation of nitrous gas, which will render its presence sensible by the dense red fumes that will arise from the mixture. If the operator perceives this effect coming on, he must immediately so stir the portions of cotton when it occurs that the acid may be brought into immediate contact with the fibre, to the exclusion of the air contained or entangled in the interstices of the cotton, otherwise a deterioration in the resulting pyroxyline will take place. When the cotton has been immersed for 10 or 15 minutes, it is to be removed to a capacious vessel of cold water and stirred about with a stick for a few minutes;

the water must then be changed three or four times until the whole of the acid is removed from the pyroxyline; this may be ascertained by throwing into this last water a piece of blue litmus paper, which will indicate whether the liquid be acid in its reaction or not. When the gun-cotton or pyroxyline is entirely freed from all trace of acid, it is to be squeezed, so as to get rid of as much moisture as possible, and is then to be spread out in a warm place to become dry. The drying will be much facilitated if carried on in a current of air; as a matter of precaution, it will be better not to dry the pyroxyline by the fire, for fear that an explosion might occur from some portion becoming dry and more easily inflamed by the proximity of the source of heat. Cotton treated in the manner above described should not be much altered in its texture; it should only feel more harsh to the touch, the fibre remaining much of the same length as that of the original cotton. If the fibre turns out short and easily broken, we may infer that the acids have been used of too high a temperature, or that their specific gravity has been too low. It would be well, as a matter of practice, if the operator were to confine himself to experimenting on small quantities of acids and cotton, until he is master of the appearances presented during the conversion of the cotton-wool into pyroxyline.

By following the above directions carefully, any one can ensure making a cotton that shall be perfectly soluble, and one that will give the essentials of toughness and tenacity to the collodion made with it.

The next part of the process is to bring the cotton prepared as above to a state of solution. This is accomplished in the following manner:—

Place 80 grains of the prepared cotton in a one-pint bottle, and pour on to it 10 drachms of alcohol of the specific gravity $\cdot 840$. Agitate so as to saturate the cotton with the alcohol, and then add 18 ozs. by measure of sulphuric æther, of specific gravity $\cdot 730$. Agitation must be kept up until the whole of the cotton is dissolved, which will be in three or four minutes, if it has been properly prepared in the first instance. The bottle containing the above is now to be set aside to allow the collodion to clear, which it will do in the

course of 36 hours by the deposition of some of the fine fibres of the cotton that are insoluble in the æther.

The reason of adding alcohol to the cotton before dissolving in the æther is, that it may be taken up more readily; for if we treat the cotton with very strong æther it will not be dissolved, but immediately on the addition of a small quantity of alcohol it is entirely taken up.

NEGATIVE COLLODION PROCESS.

Having prepared our Collodion as before directed, and drawn it off from the sediment in the bottle, the next point to which we turn our attention is, to impregnate it with some soluble iodide—in fact, to iodize it.

Many methods to effect this object have been published from time to time, each, according to the discoverer, possessing advantages above all others. I shall, however, confine myself to a description of the process that, after long experience, appears to me to fulfil all the necessary conditions in the most complete and simple manner.

IODIZING SOLUTION FOR NEGATIVE COLLODION.

The plan which I adopt, and one that, after repeated trials, I find is liable to fewer objections and accidents than any hitherto prepared, is, to dissolve 16 grains of pure iodide of cadmium and 16 grains of pure iodide of ammonium in 2 oz. of absolute alcohol, and after careful filtration through two thicknesses of bibulous paper, 2 drachms of this mixture are to be added to 6 drachms of plain collodion, prepared as above directed. Collodion, iodized in this manner, will be found to give excellent half-tones, and at the same time furnish negatives of great intensity and vigour, capable of producing pictures of great beauty when printed on paper.

SOLUTIONS REQUIRED IN THE NEGATIVE COLLODION PROCESS.

NITRATE OF SILVER BATH.—This bath requires great care in its

preparation, as much of the success of the process depends on its proper composition. The formula which I have used as yielding the best results is the following:—

Pure nitrate of silver in crystals	1½ ounces.
Distilled water	20 ounces.
Iodide of potassium	4 grains.

The bottle containing these ingredients is to be well shaken at intervals, and allowed to remain in a warm place for a few hours, the contents may then be filtered into a *perfectly clean* bottle for use.

Before, however, we can make sure of obtaining a perfectly clear picture in this bath, it is necessary to test it as to the degree of neutrality it exhibits, and this is accomplished by allowing a drop of the clear filtered solution to fall on a piece of blue litmus paper: if, after the lapse of a minute, no alteration takes place in the colour, we may conclude that the bath is quite neutral; if, on the contrary, the blue colour of the paper is changed to a tint verging on green, we may conclude that the bath is in an alkaline condition; and if, on a third trial, we find the litmus paper changes in tint from blue to red, we may argue that an acid condition pervades the bath. In the case of the two former conditions obtaining it is necessary to add one or two drops of *pure* glacial acetic acid to the bath, and to test it with the litmus paper between each addition until we find that the drop of bath on the blue litmus paper just changes the colour to a pink (not red); on the contrary, if on the first trial the litmus paper indicate a decidedly acid reaction, we must add, drop by drop, a dilute solution of ammonia, until the pink colour is obtained on testing with a fresh piece of litmus paper.

We have been thus explicit in the manner of accomplishing this important condition of the bath for two reasons—first, because so much of the beauty of the negatives produced depends on the state of the bath, and second, although a simple matter, there are many beginners in the art who might stumble thus early in their experiments, and ever fail to become proficient from a want of knowledge of the properties requisite in a good bath.

DEVELOPING SOLUTION FOR NEGATIVES.

The solution which I have found to give the best results, and the formula for which there appears, after long trial, no reason to alter, is composed as follows:—

Pyrogallic acid	3 grains.
Glacial acetic acid	1 drachm.
Distilled water	2 ounces.

Dissolve the pyrogallic acid in the distilled water, and then add the acetic acid. If the solution should present any appearance of turbidness, it must be filtered carefully through bibulous paper in order to render it perfectly bright and clear.

FIXING SOLUTION FOR NEGATIVES.

This consists simply of a solution of hypo-sulphite of soda in water; the quantities are noted in the following formula:—

Hypo-sulphite of soda	8 ounces.
Water (distilled or rain)	20 ounces.

There is no necessity for this solution to be filtered except to free it from any gross impurities.

The solutions being all prepared, we shall next proceed to give as detailed and simple an account as possible of the manipulatory part of the process; and let me here impress upon the mind of the novice in such matters, that next to ABSOLUTELY PURE CHEMICALS, cleanliness is of the highest importance, and that he cannot hope for success unless great attention be paid to this particular.

The manipulation is divided into seven distinct operations, viz., cleaning the plate, spreading the collodion film, exciting the plate or rendering it sensitive, exposure to the action of light, development of the image, fixing the proof, and finally varnishing the picture, to prevent injury to the surface while taking the positive on paper.

CLEANING THE PLATE.

The plate, which should be ground at the edges, is to be thoroughly washed in abundance of water, dried on clean linen

cloths, and finished by being rubbed with a piece of perfectly clean wash leather, one that has been passed through several clean waters to free it from the dressing that exists in it at the time of purchasing.

There is no occasion whatever for the use of nitric acid, potash, soda, or ammonia; all of these substances increase the chances of accident, without giving a corresponding equivalent in their cleaning qualities.

If any difficulty arises in getting a perfectly clean plate, a few drops of old waste collodion applied to the surface with a piece of cotton-wool will easily accomplish it; the cleaning is to be finished with the wash-leather as before.

The plate being thoroughly clean, we proceed to the second operation—

SPREADING THE FILM.

This is best accomplished in the manner following:—Hold the plate by the corner (A, *Fig. 3*) between the thumb and forefinger of the left hand, and having previously freed the collodion bottle from any particles of dry collodion which may be adhering to it, pour a good quantity of the collodion on the plate at about the point (E); then by gently tilting the plate, firstly towards the corner (c), secondly to (D), then to (A), taking care that the collodion does not touch the thumb, and lastly to (B), we shall find the plate perfectly covered with the film, and the superfluous quantity in the best position for returning to the bottle, which being done, the plate is still to be kept slightly inclined so that the corner (B) may be lowest; and the lip of the bottle is to be drawn gradually in contact with the edge of the glass from (B) to (A), in order to correct in a great measure the tendency which the collodion has to form streaks across the glass plate: this it accomplishes by laying hold as it were of the film, and shifting its position slightly on the surface of the glass. The operation of coating the plate ought to be performed as quickly as possible, as the evaporation which takes place from such

an extended surface of collodion gives rise to the loss of so much æther as to render the collodion returned from the plate almost useless, if the operation be delayed beyond a certain time.

The accompanying cut (*Fig. 4*) will convey an idea of the way in which the plate is to be held; in the drawing we are supposed to be facing the operator.

Fig. 4.

RENDERING THE PLATE SENSITIVE.

Fig. 5.

As soon as the collodion film has become set, the plate is to be placed on the dipper, and immediately plunged into the nitrate of silver bath (*Fig. 5.*) This must be done at one stroke: there must be no stoppage during its descent into the bath; otherwise, wherever such pause has taken place there will be a line on the picture, which will give evidence of its existence in the subsequent part of the process.

After leaving the plate immersed for about half a minute, withdraw it carefully; the surface will have changed its aspect, and become of a yellowish colour, and will furthermore be covered with streaks, just as if the plate had been previously oiled. It must be immediately returned to the bath, and moved once or twice briskly up and down at intervals through the space of two minutes when the thermometer

is at about 60° Fah , but if lower, longer time may be allowed in the bath. It will be found on removal that the whole of what is technically called greasiness is gone off, and that the liquid flows quite freely over the surface.

The plate is now removed from the bath, and held with one corner downwards to drain for a moment or so: it is then ready for placing in the dark frame of the camera.

Great difficulty, I am fully aware, is experienced by beginners in knowing how long the plate, after having the collodion poured on to it, ought to remain before immersion in the bath. This difficulty, like many others, will vanish in a very short time, if proper attention be devoted to the appearance of the film under different circumstances. For instance, if the operator finds that it takes some considerable time before the film becomes of an opalescent hue, he may safely conclude that the plate has remained out of the bath for too long a time; if, on the contrary, there is any tendency of the iodide of silver formed on the plate, immediately on its immersion in the bath, to wash off—as is not unfrequently the case, especially at one of the corners—he may assuredly predict that the collodion has not become set, and that in future operations with that collodion, he must allow a longer period to elapse before immersing it in the bath. A very few experiments will suffice to show the truth of these remarks, and also the necessity for great caution in manipulation. It must always be remembered, after we have been working from one bottle of collodion for any length of time, that the æther has considerably diminished in quantity, in proportion to the alcohol present in the collodion; so that we shall have to defer the immersion of the plate in the bath, in proportion to the amount of exposure the collodion has had in our previous operations. This may appear to many a point of minor importance, but it is scarcely credible the stumbling-block it is in the path of the inexperienced.

Another difficulty experienced by the uninitiated is, the length of time that the plate should remain under the action of the bath, in order to give it the greatest amount of sensitiveness. This varies with the temperature, and appears to be entirely dependent upon it; but it will be found that at the temperature of 60° Fah., two minutes is

quite sufficient to render the film sensitive. If, as stated before, the thermometer falls below 50° Fah., longer time—say from three to four minutes—must be allowed to elapse before the final removal of the plate from the bath; but, on the contrary, if the temperature be considerably above 60°, as in the height of summer, the time of immersion must be curtailed in proportion.

Having pointed out these difficulties, and also indicated a way to surmount them, we must leave it to the industry and judgment of the operator to prevent their recurrence, and consider that he has prepared his plate ready for the next step in the process—

EXPOSURE IN THE CAMERA.

This is a point of the greatest nicety, and one which taxes the judgment of experienced operators very severely, especially in a climate like ours, where there is a continual variation in the intensity of the light.

In the case of a portrait, the sitter ought to be so placed that he may be well and equably illumined, taking care that one side of the face is in comparative shadow, and also that the eyes are protected by blinds, or some contrivance, from any great glare of light, which would inevitably give a false expression to the face, and consequently spoil the likeness. The aspect best adapted for the purpose is the northern, which, of course, is free from the glare complained of, and at the same time reflects light of superior photographic quality.

Care should be taken that the sitter does not move during the operation: this is best accomplished by having the chair furnished at its back with a head rest (*Fig. 6*), which will prevent the nervous jerk we are so apt to give when sitting in one posture for a few moments together.

The figure being posed to our satisfaction, it is necessary to bring the image to a focus on the ground glass of the camera, and this should be done carefully, as much of the success depends on its proper adjustment.

Fig. 6.

We now proceed to expose the plate to the action

of the light passing through the lens. The precise time of exposure must depend entirely on the judgment of the operator; all we can do in the matter is, to give such general directions as may assist in forming it, and we cannot do better than by instancing cases of *under-exposure* and *over-exposure*. If we find on developing the image that the parts of the picture that were in the best light—such as the forehead, the shirt-front, &c.—make their appearance with some difficulty, and that the parts not so well-illuminated fail to be at all perceptible, we may conclude that the plate has been under-exposed; but if, on the contrary, the parts that were in comparative shadow are developed as soon as the high lights, we shall find that too long an exposure has been given to the sensitive plate.

The way in which a picture develops itself that has undergone the right amount of exposure is—first, the shirt-front appears; next, the forehead and the light side of the face; then, the parts which are not so well-illuminated; and lastly, the deep shadows become developed.

It is a curious fact, that a picture that has been over-exposed, instead of being extremely dense, as we should naturally expect, loses its vigour in a remarkable degree. While we are viewing it by reflected light, it appears a most solid and vigorous proof; but, on holding it between the eye and the light, we shall at once find that the high lights of the picture are scarcely more dense than the background; and instead of a picture that would give a good positive on paper, we shall have one that will scarcely bear printing at all.

We must suppose that the plate has been exposed properly in the camera, and that we are about to

DEVELOP THE PICTURE.

Fig. 7.

In order to do this, we remove it carefully from the dark slide, and place it face upwards on the levelling stand (*Fig. 7*), which has been previously adjusted by means of the screws mentioned before. We now prepare the solution by placing in the small measure, for the 5 in. by 4 in. plate, 10 drops of nitrate of silver solution, of the strength of

50 grains to the ounce, adding thereto 4 drachms of the developing solution for negatives, at page 17. This mixture is then to be poured over the plate as quickly as possible, so as to bring every part under its influence as soon as practicable. As this is a point of some nicety in the manipulation, it may be as well to endeavour to describe as accurately as we can the mode of procedure. Take the measure in the right hand, and beginning at the right hand corner nearest to you, pour on the solution, giving the hand while performing the operation somewhat the motion that would be required for throwing a quoit: this must not be done too quickly nor with too great force, otherwise stains will appear on the plate at that point where we first poured on the developing solution. The reason of this is, evidently, the forcible removal of the film of nitrate of silver still adhering to the plate after its immersion in the bath when being rendered sensitive.

The picture will begin now to appear: the high lights will first come out, then the half-tints, and lastly, the deeper shadows.

During the time that all this is taking place, it is necessary to keep the fluid in motion, in order that the action may be more equal all over the plate. This is best accomplished by gently blowing on the surface in different parts, taking care that it is so gently done that no part of the plate is left dry for any time, no matter how short. It can be ascertained when the picture is sufficiently developed, by simply holding a piece of white paper underneath the glass plate in such manner that the light reflected from it may traverse the impression. If the operation has been continued sufficiently long, the dark parts will have an intensity according to the exposure, and the parts where the light has not acted will be perfectly transparent and clear; but if, on the contrary, the plate has been subjected to too long an action of the developing solution, the parts that ought to be clear will present a muddy appearance, and there will be a deposit of silver in a minute state of division all over the plate; and further, there will not be that fine variety in the half-tones which characterise a good and successful negative.

During the development, the solution on the plate ought not to become muddy, otherwise the picture will be devoid of clearness. If the operator find that such an effect is coming on, he had better

prepare a second quantity of developing solution, precisely the same as at first, and having washed off the discoloured and dirty solution from the plate, pour on that freshly made. Great intensity may by this means be obtained without the danger of the clouding over of the light parts by the deposition of silver in the metallic state.

THE FIXING PROCESS.

Having poured off the developing solution, the plate is to be washed in a gentle stream of water, and being replaced on the levelling stand, a quantity of hypo-sulphite of soda (page 17) is to be poured over it, and allowed to remain on until the whole of the yellow iodide of the parts unacted upon by light is entirely dissolved. When this effect, which is readily perceived, is brought about, the plate must be washed in abundance of water, poured very gently over it. Care is required in this operation to prevent the film from being broken, and also from being washed off. The former mishap may be prevented by pouring the water over the plate from a very small elevation, and the latter by not allowing the stream to play on any part of the film that is not attached to the extreme edges of the glass plate.

VARNISHING THE PLATE WITH SPIRIT VARNISH.

Before we can print with safety from the negatives obtained by the collodion process, it is necessary to protect the film from injury, and at the same time to take care that the varnish that we use possesses the qualities of transparency and hardness. The varnish I employ is composed of gum sandarach dissolved in alcohol, and the best mode of applying it is to warm the plate gently by the fire to prevent it from becoming chilled; then pour on the varnish in the same manner as recommended while treating of the collodion film, returning the superfluous quantity to the bottle. A fragment of blotting paper is to be passed along the edge of the glass where the varnish has become thickened, in order to remove the same. On holding the varnished side of the plate to the fire for two or three minutes, the varnish will become quite dry, and when cold will be perfectly hard.

The precautions necessary in the varnishing process are, first, not to make the plate too hot before coating it with varnish, as this causes it to crack at some subsequent period; second, not to allow the plate to get cool before the varnish is quite dry, otherwise, instead of a beautifully hard transparent film, we shall have one nearly opaque and of a granular appearance, owing to the varnish having become chilled. If the varnishing operation has been skilfully conducted, there is a great difficulty in determining on which side of the glass the picture has been formed, without referring to the corner by which the plate has been held.

VARNISHING THE PLATE WITH BENZOIN VARNISH.

Although the above plan answers perfectly, it is not always convenient to have a fire at hand in order to warm the plate; we have therefore devised another varnish, called Benzoin Varnish, in which the solvent is chloroform, which does not require the plate to be warmed. This varnish is applied to the plate in the same manner as collodion, and the superfluous quantity being returned to the bottle, the plate is dry in a few seconds; the film being protected by a beautiful hard film of varnish.

We cannot overrate the value of this preparation, for, from the ease with which it is applied, and the certainty of a successful result, it is invaluable in the hands of the amateur.

POSITIVE COLLODION PROCESS.

THE Positive Collodion Process having of late become so exceedingly popular, from the ease and readiness with which the finished pictures are obtained, we propose to devote a separate article to the consideration of the details of the process.

IODIZING SOLUTION FOR POSITIVE COLLODION.

The iodizing solution that has succeeded best in the hands of the Author, and one that gives most excellent results with the collodion prepared as before described (page 14) is composed in the manner

following:—12 grains of iodide of ammonium and 12 grains of bromide of ammonium are to be dissolved in 1 oz. of absolute alcohol, and carefully filtered through two thicknesses of bibulous paper; 2 drachms of this iodizing compound are to be added to 6 drachms of collodion, prepared as before indicated. When the collodion thus iodized has become quite clear, it is ready for use; this will be in about 12 hours.

SOLUTIONS REQUIRED IN THE POSITIVE COLLODION PROCESS.

THE BATH.—The bath for rendering the plates sensitive is very simple in its nature, being composed of

Nitrate of silver, in crystals	800 grains.
Distilled water	20 ounces.
Nitric acid	10 drops.

When the crystals are dissolved, a drop of the solution is to be allowed to fall on a fragment of blue litmus paper, and its effect carefully noted; if it fail to immediately change the colour to a full pink verging on red, we may conclude that the bath is not in a sufficiently acid condition to produce clear and brilliant pictures. In order to bring about this result, it is necessary to add a few more drops of nitric acid and testing with the paper between each addition, until the desired tint is obtained.

To recapitulate, we may remark that a good positive collodion bath ought to have a very perceptibly acid reaction on litmus paper.

DEVELOPING SOLUTION FOR POSITIVES.

There have been almost as many solutions proposed for the purpose of developing the positive collodion picture as there are operators; the chief difference, however, will be found to consist in the proportions of ingredients rather than in a great diversity of substances. I have experimented on all known solutions, and can obtain good pictures with many of them, but I have been led to the adoption of the following formula, from its extreme simplicity and

the ease with which it is prepared, and the beautiful and exquisite tones it gives to the picture.

The solution is composed as follows :—

Proto-sulphate of iron	3 ounces.
Nitrate of baryta	2 ounces.
Nitric acid	$\frac{1}{2}$ ounce.
Distilled water	40 ounces.
Alcohol sp. gr. '840	2 ounces.

Dissolve the proto-sulphate of iron in one-half of the water, and the nitrate of baryta in the other half, and add the two solutions together, allow the precipitate to settle, filter, and then add the nitric acid and alcohol.

FIXING SOLUTION FOR POSITIVES.

The fixing solution for positives is composed according to the following formula :—

Cyanide of potassium	40 grains.
Distilled water	10 ounces.

When dissolved, filter carefully for use.

The positive collodion process divides itself naturally into seven distinct steps, namely, cleaning the plate, coating the plate with collodion, exciting or rendering the plate sensitive, exposure in the camera, development of the latent image, fixing the picture, and, lastly, varnishing and backing the picture.

Before entering on the details of this beautiful process, let me remind the beginner, that in order to insure success, he must be scrupulously clean in all his manipulations; the cloths he uses for cleaning the plates must be absolutely free from impurity, and every care must also be taken to prevent the access of white light to the surface of the plate after it has been rendered sensitive.

Bearing these remarks in mind, he may proceed to

CLEANING THE PLATE.

In the positive process, the plate requires to be free from the slightest impurity; it is not only necessary that it should appear

clean, but it must be chemically so. The plan most to be recommended is, to lay the plate on a piece of white blotting paper and pour on it a few drops of old waste collodion. This is to be rubbed over the plate on both sides with a small pledget of cotton wool, using a brisk circular motion of the hand; this will remove all extraneous matters, and the plate is to be then well washed under a stream of water, and immediately dried on a linen cloth, and finished with a perfectly clean wash-leather. The plate being now clean, and perfectly free from every impurity, we proceed to the next operation—

COATING THE PLATE.

This is accomplished in precisely the same way as in the negative process (a detailed description of the manipulation will be found at page 18); the same precautions are necessary in both processes, the object being to spread the film in a perfectly even manner over the glass plate.

RENDERING THE PLATE SENSITIVE

Forms the next step in the process. When the collodion film has become set, the plate is to be placed on the glass dipper, and plunged, without hesitation, into the nitrate of silver bath; after a lapse of not less than half a minute, the dipper with the plate is to be withdrawn, and immediately returned to the bath. During the interval that the coated surface remains out of the bath in this operation, we shall observe that the film has become of an opalescent hue, and that the surface of it exhibits innumerable streaks running down from the top to the lower edge of the plate; these streaks are caused by the æther remaining in the film, and must be removed by moving the plate briskly up and down through an interval not exceeding two minutes. On examining the state of the surface at this stage of the proceeding, we shall find that the liquid composing the bath flows quite freely and evenly over it. The plate is now ready to be placed in the dark slide of the camera to await

THE EXPOSURE IN THE CAMERA.

This is a point of the greatest nicety in the whole process, as so much of the beauty of the picture depends on the correct amount of exposure being given to the plate, and, unfortunately, the Author is not in a position to give any definite directions on this head, owing to the varying circumstances under which a picture may be taken; he is therefore compelled to have recourse to the same mode of instructing the judgment of the operator as he adopted while treating of the negative process, namely, by giving instances of over-exposure and under-exposure. In a plate when subjected to the action of the developing agent, that has not undergone the proper amount of exposure, the following peculiarities will manifest themselves:—the parts of the object which have been most highly illumined will, after a moment or so, make their appearance, and then, after a considerable lapse of time, we shall perceive the parts slightly less illumined coming out, but no matter how long we continue the development, we shall fail altogether to distinguish a trace of the deeper shadows of the picture.

On the contrary, in the case of a plate that has been over-exposed, a very different set of phenomena will present themselves. Immediately on applying the developing solution, the whole of the picture will make its appearance at once, the deep shadows coming out as soon as the high lights—these assuming undue prominence—and, further, after treatment with the cyanide of potassium, and subsequent washing with water, there will be an absence of half tone in the light portions of the picture; and in the instance of a portrait, the face will appear almost flat, the features scarcely being distinguishable, owing to the blending of the lights of the picture with the shadows: the reason is obvious—the shadows which ordinarily possess but little depth have been exposed to too long an action, and have become nearly as forcible as the high lights, which in their turn are incapable of attaining any greater brilliancy, no matter how long exposed to the solar radiations—consequently, we lose the contrast, and obtain only a flat map instead of a perfect portrait.

The picture which will follow the application of the developing

agent, if the operator has been happy in the judgment of his time, will present none of those peculiarities above mentioned, but, on the contrary, the high lights, as a matter of course, will be the first to appear; then the half-tones, visibly inferior in strength; and, lastly the shadowy parts will be faintly visible.

From these observations, the operator will, doubtless, after a little practice, be enabled to judge of the time of exposure with sufficient accuracy to ensure good results.

We must imagine that the plate has undergone the exposure in the camera, and awaits the next stage of the process, the

DEVELOPMENT OF THE LATENT IMAGE.

The plate, on removal from the dark slide of the camera, is to be placed on the levelling stand (page 22), the screws of which have been so adjusted that the plate may have an extremely slight inclination from right to left; the position of the plate is represented by this line (A B)  A Then having placed

the developing solution in a measure glass, it is to be carefully poured along the upper edge of the plate, namely, at (A), as quickly as possible; the inclination of the plate will cause the liquid to diffuse itself all over the plate in a continuous stream, and will prevent the formation of stains and streaks, which would be likely to occur if the developing solution was applied in the way described for negatives (page 23).

When the developing agent has completely covered the plate, the picture will begin to make its appearance, the high lights coming out almost immediately; then the half-tones; and, lastly, the parts that were in deep shadow will give indications of their presence. When this point is reached, the solution must be thrown off the plate, and an abundant supply of water run over its surface, in order to prevent the decomposition of the cyanide of potassium, which would take place from the action of the acid in the developing solution, when

FIXING THE PICTURE.

When the plate is quite free from the developing fluid, it is

returned to the levelling stand, and the solution of cyanide of potassium is applied so as effectually to cover the surface; this is for the purpose of dissolving the iodide of silver which forms the sensitive surface.

It is most beautiful and interesting to notice the mist, as it were, gradually being dispelled by the cyanide, and the brilliant picture stand out in bold relief against the back ground: photographically speaking, I know of no greater pleasure than to see a successful picture gradually making its appearance from the clouds that have enveloped it up to this point; it well repays you for many failures and vexations in the earlier part of your photographic career.

When the picture is quite free from the iodide of silver, it is to be washed in a gentle stream of water, and allowed to dry, to await the next stage in the process—

VARNISHING AND BACKING THE PICTURE.

For positives, the surface of the collodion must be varnished in the same manner as directed while treating of negatives (page 24), although, in this instance, crystal varnish is to be preferred to the spirit or benzoin varnishes, as the colour of the picture is less altered by it. It is applied in the same manner as the benzoin varnish (page 25), but it requires a longer time to become dry.

When the varnish is quite dry, the plate is to be warmed, and a black varnish, called LIQUID JET, is to be poured over the back of the plate, observing the same precautions as with the transparent varnish; the only difference in the manipulation being, that the plate that has been coated with black varnish must be placed in the neighbourhood of a fire—for instance, on the hob—for about a quarter of an hour, in order that the varnish may get perfectly dry before it is handled.

For the production of positive pictures on paper, we refer the reader to the section devoted to that subject (page 61).

FAILURES AND THEIR CAUSES.

UNDER this head, I purpose to enumerate the principal instances of failure in the Collodion processes, both Positive and Negative, and to

endeavour to point out the cause of each, with a view to its correction, and I have no doubt but the beginner in Photography will be glad to have an article like the present to assist him in discovering the cause, and indicating a remedy in any case of failure that may occur in his own practice.

In order to make the subject more clear, and to enable the operator to refer the failure he may have met with to its proper cause, I have considered it best to divide the failures into classes, namely, those dependent on the condition of the collodion, those having relation to the state of the nitrate of silver bath, those from improper exposure in the camera, and, lastly, those from peculiarities in the developing solutions.

To secure perfect clearness, moreover, it is necessary to consider *separately* the conditions under which negatives and positives on glass are produced.

THE NEGATIVE PROCESS.

FAILURES ATTRIBUTABLE TO THE CONDITION OF THE COLLODION.

The collodion, when in good condition, ought to be quite clear, or, at least, free from any floating particles of insoluble matter; if this be not the case, when it is poured on the plate, the insoluble portions will become fixed to the surface, and the fluid collodion, passing round them in its passage back to the bottle, will produce irregular patches in the surface: these can be clearly seen when the plate comes from the bath, and a plate so defaced ought not to be used, as it is sure to be developed with a stain or mark, indicating the position of the insoluble matter let fall from the collodion.

The remedy in this case is obvious, for by allowing the collodion to remain at rest for some hours, all insoluble matters will fall to the bottom of the bottle, and the clear portions can be decanted into a clean dry bottle for use.

DIAGONAL STREAKS ACROSS THE PLATE are caused by the collodion being too thick, and not flowing quite freely over the plate; this

occurs from the evaporation of the æther, either from the high temperature of the atmosphere, as in summer, or from the sample under consideration having been used for covering a great number of plates; in either case, the remedy is the same, namely, to add sufficient sulphuric æther of the specific gravity $\cdot 750$, to bring back the collodion to a condition in which it will flow evenly over the plate; the æther should be added a little at a time, and a plate spread between each addition, as a test for the quantity required.

ABSENCE OF HALF-TONE in the picture is caused by the iodized collodion with which it is taken having undergone a slight decomposition from keeping, which renders it very slow in its action, and insensible to weak luminous radiations, such as emanate from the shadows of a picture: the cause is not—as has often been erroneously stated, the liberation of free iodine (causing the collodion to appear red)—but is owing to a decomposition that has taken place in the collodion itself when mixed with the iodizing solution, the quantity of alcohol present in the collodion determining the amount of decomposition.

FAILURES ATTRIBUTABLE TO THE STATE OF THE NITRATE OF SILVER BATH.

Of all the misfortunes that can possibly befall the collodion operator, perhaps there is none which gives so much trouble as the fogging of the pictures; probably this arises from an imperfect knowledge of the causes that bring about this state of the plate, but in all cases it may be referred to the state of the bath. For negatives, the bath ought to be in a slightly acid condition, and exactly saturated with iodide of silver; when these conditions are obtained, the bath will yield clean and perfect pictures on development; but if, from any cause, the bath should have become alkaline—that is to say, when tested with litmus paper, fails to give an acid or neutral indication—then the plates all become fogged under the action of the developing solution. This fogging may be explained as a clouding over the parts of the picture that ought to be transparent, and when positives are printed from fogged negatives, a great want of contrast is always observable in them. The immediate cause of this veil or cloud over

the picture is the decomposition of the iodide of silver by the developing solution, independently of the action of light; and tracing the matter to its source, we find that the real cause of the fogging is, that the iodide of silver precipitated from an alkaline bath is decomposed by the developer, while that precipitated on a plate in the presence of an acid—that is, in an acid bath—is entirely unacted upon by it: thus we have explained at once the cause of this most troublesome failure. The remedy is simple in the extreme—we have only to add, drop by drop, the best and purest glacial acetic acid, until the litmus paper indicates a slightly acid re-action, as described at page 16.

But, independently of the above causes of fogging, there is another, which, until its remedy is known, is apt to give great annoyance; it is the fogging that comes on mostly in very warm weather, more especially if the bath has been allowed to evaporate; it is fogging by super-saturation of the bath with iodide of silver: under these circumstances the bath may be perfectly clear and indicate an acid re-action, and yet the pictures are all fogged, and this is to be attributed to an excess of iodide of silver in the bath.

The remedy in this case is to add to the bath about a sixth part of its volume of distilled water, this will cause a milkiness in the solution from a precipitation of iodide of silver; pass the bath in this state through a filter, and add to the clear solution as much nitrate of silver in crystals as would be sufficient to make it of the proper strength, namely, 30 grains to the ounce; thus if we add 4 oz. of water in the first instance, we shall have to throw into the clear filtered bath $\frac{1}{4}$ oz. of nitrate of silver. If we now take a picture on a plate prepared in this bath we shall find it quite free from fog or cloudiness.

STREAKS DOWN THE PLATE.—After the immersion of a number of plates in a nitrate of silver bath, we shall find, on testing it, that it contains a considerable amount of æther, which it has acquired from the successive films on their immersion; now when this æther exists in the bath beyond a certain proportion it gives rise to streaks on the plate, for it is impossible to get the solution to flow freely over the surfaces of the plate in a bath in which there is an excess of æther.

The remedy in this case is either to allow the bath to be exposed to the air for some time, or, what is better, to place the bottle into which it has been turned in a vessel of hot water for half an hour or so; this will cause the æther to evaporate and the bath will be restored to its former condition.

DUST ON THE SURFACE OF THE BATH will give rise to a number of blemishes on the plates, the kind varying with the nature of the deposit; if the bath has been allowed to be exposed to the air and light for some days, the surface will be covered with a thin layer of pure silver, this will cause stains over the plate immersed in a bath so circumstanced, but the most frequent difficulty met with arises from the dust of the room settling on the surface; if a plate be immersed when the surface of the bath is covered with dust, it will be found that, as it descends into it, the particles attach themselves to the surface of the film and are carried down with the plate; these do not wash off, but adhere firmly, and, on developing a picture taken on a plate prepared in this way, we shall have a series of lines composed of black spots running from the bottom of the plate to the top, in fact, following the direction of the immersion in the bath. This difficulty is obviated by filtering the bath, or by carefully drawing over its surface a piece of perfectly clean bibulous paper; this will remove the particles of dust and the cause of failure at the same time.

SLOW ACTION OF LIGHT ON THE FILM.—It sometimes happens that after working with a collodion that we know to be sensitive, we cannot obtain a picture under a very lengthened exposure, and then the high lights predominate to an undue extent; the cause of this will be found in the bath being in a condition of too great acidity; the litmus paper when dipped into it will turn immediately of a full red colour. The remedy under these circumstances is to add ammonia drop by drop until the overcharge of acid is corrected, which may be ascertained first by the test paper, but more correctly by taking a good picture having its half-tones perfect with a short exposure to light.

FAILURES ARISING FROM IMPROPER EXPOSURE IN THE CAMERA.

Failures that arise from this cause are not numerous—the principal

ones, namely, over-exposure and under-exposure, are fully detailed while treating of the negative process, (page 22). There is one, however, which may occur sometimes, more especially while taking views, namely, that of the formation of a film or mist before the picture; this is caused by the action of the diffused light in the camera on the surface of the film, and is quite a distinct kind of fog from that produced by the alkalinity of the bath. The remedy is to place a smaller stop in front of the lens, in order to shut out as much extraneous light as possible.

FAILURES DEPENDENT ON THE DEVELOPING SOLUTION.

The developing solution being very readily decomposed, ought to be mixed fresh and fresh, otherwise it is apt to lose its power of reducing the iodide of silver that has been acted upon by the light, and this will be found the cause of pictures, which from all other circumstances ought to be good and vigorous, coming out a dull colour, and which do not admit of being strengthened by the addition of nitrate of silver.

As soon as the developing solution becomes discoloured it ought to be rejected, for when the nitrate of silver is added to it and thrown on the plate it immediately decomposes the nitrate of silver on the surface, and gives rise to a sandy deposit of silver which it is impossible to remove by subsequent washing. Another test as to when this effect is coming on is, that the solution on the plate when blown upon as directed (page 23), exhibits patches of a silky lustre, owing to the reduction of the silver to a metallic state.

SPECKS OVER THE PLATE.—These are caused by particles of metagallic acid, which is sometimes present in a sample of pyrogallie acid. This impurity is removed by filtration of the developer through bibulous paper.

THE POSITIVE PROCESS.

FAILURES ATTRIBUTABLE TO THE CONDITION OF THE COLLODION.

The Collodion used for taking positive pictures ought not to be too freshly iodized, otherwise the pictures will be dirty, and not possess that clearness of outline that distinguishes a good positive.

Comets and specks of all kinds are caused by insoluble particles floating in the collodion, and which become deposited on the plate as the collodion is poured on. The recurrence of these may be prevented by allowing the bottle containing the collodion to remain at rest for some time, and then decanting the clear fluid into a perfectly clean bottle. A tall bottle, like that at *Fig. 8*, is very useful for this purpose.

Fig 8.

DIAGONAL LINES OR RIDGES ACROSS THE PLATE are caused by the collodion becoming too thick, either from the high temperature of the atmosphere, or from having been used for too many plates. The remedy, in this case, is to add sufficient pure sulphuric æther, of the specific gravity .750 to reduce the collodion to the proper consistency, the test being when it flows evenly over the plate without ridges or lines being formed as the film dries.

FAILURES ATTRIBUTABLE TO THE CONDITION OF THE NITRATE OF SILVER BATH.

The bath for positives ought to possess a decidedly acid reaction; that is, a drop of it let fall on blue litmus paper should turn it immediately to a light red colour.

The bath, also, must be carefully filtered from time to time, and ought to be quite clear and bright before being used.

The greatest difficulty the operator, in the positive collodion process, has to contend with is the fogging of his pictures; that is, the formation of a veil or mist over the details of the picture, which effectually obscures them. The causes of this fogging are two-fold, each depending on a certain condition of the bath: thus we have

fogging produced by the bath assuming an alkaline condition, which may be detected by litmus paper which has been slightly reddened by acetic acid, changing to its original blue colour after being moistened with the bath. The remedy for this evil is the addition, drop by drop, of nitric acid, until the acid reaction of the bath is again established.

The other cause of fogging is the bath becoming saturated with iodide of silver; this, more especially, shows itself in hot weather, or after the bath has been exposed to the air for some time. The bath becomes saturated by dissolving a portion of the freshly-formed iodide of silver from each plate during its sojourn in the liquid. The remedy, under these circumstances, is to add to the bath about a sixth part of its volume of distilled water; this will cause a deposit of the iodide of silver. The turbid solution thus formed is then to be filtered, and sufficient quantity of nitrate of silver, in crystals, is to be added to the clear solution, to make the bath up to its original strength, namely, 40 grains to the ounce.

WANT OF HALF-TONE in positives on glass is due to an over-dose of acid in the bath; its mode of action is to retard the action of the light, so that the faintly illuminated parts of the object make little or no impression on the prepared plate. The addition of ammonia, drop by drop, is the remedy in this case; a plate should be tried between each addition until the required degree of neutralization is reached.

FAILURES DEPENDENT ON IMPROPER EXPOSURE IN THE CAMERA.

The failures from this cause are not numerous, and consist of under-exposed, over-exposed, and fogged plates. The peculiar points that distinguish a plate that has been under-exposed are fully discussed at page 29, as likewise those that distinguish a plate that has been exposed to the luminous influence for too long a time.

The fogging is produced by the action of the diffused light in the camera on the surface of the iodide of silver; it is quite a distinct and different kind of mist that is deposited from this cause from that produced when the bath is alkaline. The fog from diffused light, although it obscures the picture to a great extent, does not seem so thoroughly imbedded in the film as that produced from an alkaline bath.

for in some instances the whole of it may be removed by gentle friction with a piece of soft cotton wool when the picture is dry, clearly proving that its deposition is not due to any peculiarity of the iodide of silver of the sensitive film, but is merely the result of the superficial action of a feeble diffused light.

FAILURES THAT DEPEND ON THE DEVELOPING SOLUTION.

Stains on the picture, irregular stains on the back-ground or other parts of the positive picture, are mostly caused by the developing solution not being sufficiently strong, which causes it to decompose the iodide of silver of the film in an irregular manner.

Silvery appearance in the high lights is caused by an excess of nitric acid being present in the developing solution: the remedy is obvious.

Too rapid a development of the picture is caused by the developing solution being too strong, so that when we find that the picture comes out the instant the solution is applied we may argue that there is too much of the proto-sulphate of iron in the mixture and must dilute it accordingly in order to obtain good pictures.

It sometimes happens that the finished picture is covered all over with shining crystals of silver; this is due to the development being continued for too long a time, as in the instance of an under-exposed picture, when we hope to produce a good picture by continuing the development. The remedy is to give a longer exposure in the camera and to wash off the developer at an earlier period.

We have now enumerated the principal failures that may arise in the path of the inexperienced, and although they may appear to be very formidable, I should assure my readers that they do not necessarily occur; and if the directions that I have given while treating of the process be implicitly followed, I see no reason why any of them should obstruct the way to perfect success. However, such accidents and failures do arise, and my wish is therefore to point out their causes and to provide a remedy in each individual case.

THE ALBUMEN PROCESS.

APPARATUS REQUIRED FOR THE ALBUMEN PROCESS.

Pneumatic plate-holder.
 Whisk, for frothing the albumen.
 Funnel, large size.
 Levelling stand.
 Porcelain pan.
 Drying box.
 1 ounce measure.
 Minim ditto.

SOLUTIONS REQUIRED FOR THE ALBUMEN PROCESS.

Iodide of ammonium	. . .	160 grains.
Distilled water	1 ounce.
<hr/>		
Nitrate of silver	50 grains.
Distilled water	1 ounce.
Glacial acetic acid	2 drachms.
<hr/>		
Gallic acid	30 grains.
Water	8 ounces.
<hr/>		
Hypo-sulphite of soda	8 ounces.
Water	20 ounces.

THE ALBUMEN PROCESS ON GLASS PLATES.

THE only advantage in the use of albumen as a vehicle for the sensitive compounds is, that we are enabled by its adoption to use the plates in the dry state, which renders the process particularly applicable for views and such subjects as are removed from any convenient position for manipulation. The plates prepared by this process are not very sensitive, requiring a long exposure in the camera; and further, there is some little difficulty in obtaining the dark parts of sufficient intensity to make satisfactory positives.

The process of obtaining a picture on albumenized glass, divides itself into the following operations:—

The preparation of the albumen.

Spreading the same on the surface of the glass.

Drying the film.

Rendering the film sensitive to light

Exposure in the camera.

Developing the latent image, and

Fixing the picture when formed.

The various plans that have been proposed for the preparation of the albumenized plate are so very similar, that it matters very little which formula is followed; the subjoined, however, will be found to fulfil all the conditions necessary to obtain a perfect picture.

PREPARATION OF THE ALBUMEN.

Throw the whites of three or four new-laid eggs into a deep dish, and having carefully removed any opaque portions, beat them together with a whisk or a wooden fork, for two or three minutes, just to break up the structure of the mass; then add 1 drachm of a solution of iodide of ammonium (of the strength of 160 grains of the salt to 1 oz. of water) for each white of egg, and thoroughly beat up together until the whole is converted into a perfectly white froth; cast this into a funnel, in which has been previously placed a double fold of fine muslin, and covering it over to protect it from dust, allow it to remain at rest for 10 or 12 hours, at the end of which time the froth will have subsided, and have drained as a clear liquid into the bottle placed under the funnel to receive it.

SPREADING THE ALBUMEN ON THE GLASS PLATE.

This is best accomplished, after having first rendered the plate perfectly clean, by rubbing it with a mixture of tripoli and alcohol, and then thoroughly washing and drying it, by fixing the pneumatic plate-holder (*Fig. 9*) to the centre of the back of the plate; then holding the plate in the left hand in a horizontal position, pour on sufficient iodized albumen to cover it—the flow of the albumen may be directed with the aid of a glass rod, the superfluous quantity being

Fig. 9.

returned to the bottle in the same manner as if we were working with collodion. Return the plate now to the horizontal position, and if there should appear any irregularity in the film, a gentle rotary motion may be given to it—this will cause the albumen to diffuse itself evenly over the plate; when this is the case, the plate-holder may be disengaged, and the albumenized plate placed carefully in the groove in the drying-box destined to receive it, where it must remain for a few hours in order to become dry and suited for the next operation—

RENDERING THE PLATE SENSITIVE.

The following formula will be found to give the best results:—

Nitrate of silver	50 grains	} Aceto-nitrate of silver.
Glacial acetic acid	2 drachms	
Distilled water	1 ounce	

The operation of rendering the plate sensitive is performed by pouring some of the above solution into a shallow glass dish, to the depth of $\frac{1}{4}$ of an inch, and then placing quickly the prepared side of the plate in contact with it. This is best effected by resting one end of the plate quite in the bottom corner of one side of the dish, and then dexterously allowing it quickly to drop down on to the fluid, taking care that no air bubbles intervene. The plate should be allowed to rest in this position for the space of two minutes, when it is to be carefully raised, and removed to a dish of distilled water, there to be agitated for two or three minutes; it may now be stood on end in a warm place to dry, or be placed immediately in the dark frame, to await the exposure in the camera.

EXPOSURE IN THE CAMERA.

In this matter, experience is the only guide that can be depended upon; all that we can offer to the reader is what experiment has shown to be the limits of time between which the plate, as prepared above, may be submitted to the solar radiations with success. The exact time of exposure must depend on the nature of the object, the position of the sun, and the temperature of the air. In a good light, with the temperature of 60° , from 5 to 6 minutes will be quite sufficient, where the view is of a moderately light colour, such as a stone

building, *cathedral*, &c. &c.; but if a landscape be the object we desire then a much longer time—say, from 20 minutes to 30 minutes—will not overdo the picture. A very few trials will, however, do more in forming the judgment of the operator in this particular than pages of directions, which can only be framed from cases that may only have occurred to the author.

DEVELOPING THE LATENT IMAGE.

On removing the plate from the camera, it is to be placed on a levelling stand, such as recommended for the Collodion process (page 22), and treated with the solution of gallic acid; the picture will soon make its appearance, if it has had the right exposure. When the image is quite developed, but of rather a faint colour, a small quantity of gallic acid and aceto-nitrate of silver, in equal proportions, is to be poured evenly over it; this will deepen the tones and give force and vigour to the whole picture. When this point is attained, and the impression is sufficiently dark, the developing solution is to be thrown off, and a quantity of water poured over the surface, to fit it for the process of

FIXING THE PICTURE,

Which consists in pouring on to the plate the solution of hypo-sulphite of soda, and leaving it there till all the yellow colour disappears; washing the picture thus fixed with abundance of water, and subsequent drying of the plate, concludes the process of obtaining a negative on glass by means of a film of albumen.

These negatives may be printed from without being varnished, if a little care be taken that their surfaces are not allowed to come in contact with any grit, so that they become scratched. The exquisite detail of Albumen pictures forms one very great recommendation for the adoption of the process. Another advantage is, that the plates can be used in the dry state, and after being excited for several days. The only drawback appears to be, the length of exposure in the camera, and the tardy development of the photographic image, after having been subjected to the solar influence.

PAPER PROCESSES.

THE CALOTYPE OR TALBOTYPE.

The process—a modification of which we are now about to describe—was the subject of a patent granted to Mr. Fox Talbot, from whose name the second title of this paper is derived. It consists essentially of the production of pictures on iodized paper, by means of nitrate of silver and gallic acid. It is impossible, however, to obtain a successful picture by Mr. Fox Talbot's method as laid down in his specification, and it has been found necessary so to modify the plan of procedure, that it almost assumes the form of a new process.

The material on which we have to work is paper, and every care and attention ought to be directed to the selection of such samples as present the greatest uniformity of texture and evenness of surface, combined with transparency, and freedom from gross blemishes, such as iron or brass spots, &c.

APPARATUS REQUIRED IN THE CALOTYPE PROCESS.

Soft wood board.	1 oz. measure.
Glass rod.	Minim ditto.
Funnel.	Pins.

SOLUTIONS REQUIRED IN THE CALOTYPE PROCESS.

FIRST PROCESS.

Iodide of silver	30 grains.
Water (distilled)	1 ounce.
Iodide of potassium, to dissolve iodide of silver.	

Nitrate of silver	50 grains.
Water (distilled)	1 ounce.

Glacial acetic acid.

Gallic acid	4 grains.
Water (distilled)	1 ounce.

Hypo-sulphite of soda	4 ounces
Water	1 pint.

SECOND PROCESS.

Iodide of potassium	20 grains.
Water (distilled)	1 ounce.
<hr/>	
Nitrate of silver	30 grains.
Water (distilled)	1 ounce.
Glacial acetic acid	2 drachms.
<hr/>	
Gallic acid	4 grains.
Water (distilled)	1 ounce.
<hr/>	
Hypo-sulphite of soda	4 ounces.
Water	1 pint.

There are two processes by which the author has succeeded in obtaining most excellent results, and he now purposes to give such plain and simple directions in both of them, that if followed carefully and in detail, by the merest tyro in the art, must lead him to success.

The first process separates itself into the following divisions:—

Iodizing the paper.

Rendering the paper sensitive.

Exposure in the camera.

Development of the image; and

Fixing the picture.

TO IODIZE THE PAPER.

Make a solution as follows—

Nitrate of silver	30 Grains.
Distilled water	1 ounce.

Add to this a solution of 30 grains of iodide of potassium in 1 ounce of water: a brilliant yellow precipitate will be the result. Allow this to settle, pour off the supernatant liquid, and treat the precipitate with a fresh 2 ounces of distilled water; let it rest once more, and again decant the clear liquid remaining above the powder. Now pour 1 ounce of distilled water on to the iodide of silver thus formed, and add one crystal at a time of iodide of potassium (continually stirring with a glass rod) until the whole of the precipitate is dissolved; the liquid

may now be filtered through blotting paper, and preserved in a well-stoppered bottle for use. This solution is technically called "Double iodide of silver."

The paper best suited for the Calotype is that manufactured by "Turner, of Chafford Mill," or that by "Hollingworth, of Turkey Mill." Either of them allow of good pictures being produced on them. Having selected a sheet of paper, as free as possible from blemishes of any kind, pin it by two of its corners to a soft wood board (*a*, *Fig. 10*),

Fig. 10.

and laying it flat on a table, place a glass rod along its upper end, next the pins that retain the paper, holding it with the right hand; then with the left hand pour some of the double iodide of silver immediately in front of the glass rod (B), and move the same down the

sheet of paper in such a manner that the liquid may follow the rod, and give an even coating. If this be not accomplished the first time the rod is passed over the surface, a repetition of the movement will generally secure this end. Care must be taken not to press too much on the rod, otherwise the surface of the paper is liable to become injured.

The paper being thus coated with an even layer of "Double iodide of silver," is to be removed from the board, and hung up to any convenient support, to become *surface dry*. It is then to be placed very carefully, prepared side downwards, on to the surface of water contained in a porcelain pan, and allowed to remain in contact with it for ten minutes. It is then to be removed to another pan of water, and to be totally immersed in it for the space of ten minutes more; and, finally, it is plunged into a large pan of water, and there soaked for thirty minutes, from which it is cautiously taken out, and hung up to dry spontaneously.

Care is required in floating the paper on the first bath, in order to prevent the intervention of air-bubbles between the surfaces of the water and paper. The best way of obviating this difficulty is, to take the sheet of paper, one end in the right and the other in the left hand, and bending it into the shape of the letter U with the coated side

outwards, place the middle of the letter in contact with the water, and gradually lower the ends of the paper on to the surface of that fluid. The paper being quite dry, will present a beautiful primrose tint, and is ready for the next operation, which is

RENDERING THE PAPER SENSITIVE.

The solutions required for this purpose are the following:—

Nitrate of silver	50 grains.
Distilled Water	1 ounce.
<hr/>	
Gallic acid	4 grains.
Distilled water	1 ounce.

Glacial acetic acid—ABSOLUTELY PURE.

And the sensitive solution applied to the iodized paper prepared as above, is a mixture of these in the proportions indicated below:—

Distilled water	1 drachm	} Gallo- nitrate of silver.
Nitrate of silver solution	4 drops	
Solution of gallic acid	3 drops	
Acetic acid	3 drops	

Thoroughly mix.

This solution is to be applied to the iodized paper in the same manner as the double iodide, as before described, namely, by means of the glass rod. After it has been allowed to remain on the paper for two minutes, the superfluous quantity is to be carefully removed by means of *perfectly clean* bibulous paper, and the paper, if not required to be used immediately, can be hung up to dry in a dark place. Paper prepared in this manner will keep good for 24 hours; that is to say, it may be prepared in the evening of one day, and the picture be developed in the evening of the next, without any detriment to its perfection.

We now proceed to the

EXPOSURE IN THE CAMERA.

This part of the process requires attention, and it is only by observation and experience that we can determine the time required under different circumstances. On a moderately bright day, with an

average landscape, the time of exposure would vary from five minutes to ten; the exact amount depending on the nature of the objects, and their degree of illumination. In very dull weather, from 15 to 20 minutes may with advantage elapse between opening and closing the lens; but even with this long exposure, pictures are never so satisfactory as when taken on a bright sunny day.

BRINGING OUT THE PICTURE.

The paper when it comes from the dark frame of the camera presents usually an uniform surface, no trace of the picture being visible. It is again pinned to the soft wood board, and by means of the glass rod the solution of gallic acid is spread over it, taking care that the whole of the paper is equally wetted. After a few minutes the latent image will begin to unfold itself in a most remarkable and beautiful manner—the sky, as might be supposed, coming out first—then the most highly illumined portions of the picture—and, lastly, the deep shady parts make their appearance. While this is taking place, the rod must frequently be passed over the paper, to equalize the action of the gallic acid, and also to prevent any part of the paper from becoming dry. When all the picture is developed, but is still of a light colour, a few drops of gallo-nitrate of silver may be added, and quickly spread over the paper; this will have the effect of deepening the tone of the impression, and of giving due preponderance and intensity to the dark parts of the negative.

Judgment must be exercised so as not to carry the development too far, otherwise the light parts of the picture suffer, and become charged with a deposit of oxide of silver, which greatly affects the beauty of the positive impression taken from it in the subsequent part of the process. The degree of development may be ascertained by carefully lifting the picture by one corner, and interposing it between the eye and the light; it will be seen by this means whether the “blacks” of the impression are sufficiently decided and vigorous, and also whether the detail possesses sufficient intensity to give its due effect in the positive.

As there is great latitude in the amount of time we have indicated

for the exposure of the paper to the action of light, it may be perhaps of some service to the novice to point out the effects of "under and over-exposure." If the paper, on the one hand, has been too short a time under the influence of the light, it will be some considerable time before any appearance of an image will manifest itself when being treated with gallic acid, and the shadowy parts will with great difficulty come out, even if they do at all; but, on the other hand, if too long an exposure has been given, the picture will be visible on the paper before the application of the gallic acid, and on being subjected to the process of development as before described, will assume a red tinge, instead of the beautiful and intense black so characteristic of a negative that has undergone the correct time of exposure. Fixing Bath (see page 51.)

SECOND PROCESS.

This mode of operating presents many advantages over the former, the principal of which are simplicity, ease in management, absence of necessity for so much washing of the paper, &c

Before proceeding to describe the exact plan of manipulation, I purpose to indicate what I consider the principles that ought to guide us in the production of a sensitive Calotype paper.

If we precipitate an iodide of silver from a solution of the nitrate, with an excess of iodide of potassium, we obtain a beautiful primrose powder, which, on exposure to light, does not show the slightest alteration in its properties; clearly indicating that this particular compound of iodine and silver is insensible to the influence of solar radiations.

But if, in a second experiment, we cause a precipitation of iodide of silver from a solution of the nitrate, with a deficiency of iodide of potassium, we shall obtain a different coloured powder, which being spread upon paper, and subjected to solar influence, will at first turn brown, and, gradually deepening in tone, will finally assume a tint verging on black. It is quite clear that this latter compound is different in its behaviour, under the same conditions, to that before described; and, further, that from its mode of preparation, it is of different composition. Now, it is this latter compound (the

sub-iodide of silver) that it is our endeavour to form on the paper in the Calotype process, previously to its exposure in the camera, and this end will be brought about in the most perfect manner by the following method of operation :—

PREPARATION OF THE PAPER.

Pin the paper by two of its corners to the soft wood board, and spread over its surface, by means of a glass-rod (page 46), a solution composed of

Iodide of potassium	20 grains.
Water	1 ounce.

Filter carefully before use.

After the paper is thoroughly covered, allow it to rest for two minutes, and then with a piece of perfectly clean blotting paper absorb the superfluous quantity, so as to leave the paper just surface dry; return it to the board, and having again secured it by means of the pins, repeat the operation with the aceto-nitrate of silver, prepared as follows :—

Crystallized nitrate of silver	30 grains.
Distilled water	1 ounce.
Glacial acetic acid, absolutely pure	2 drachms.

This solution is also to be suffered to remain on the paper for the space of two minutes, after which interval the outstanding liquid is to be removed by bibulous paper applied with a very light hand. This latter precaution is necessary in order to prevent the forcible removal of the sub-iodide of silver from the surface of the paper—an accident of no unfrequent occurrence, if the blotting paper be applied too roughly.

If not required for immediate use, the paper thus iodized and rendered sensitive, may be hung up to dry, or may be placed while still damp in a dark frame, to await the exposure to the action of light in the camera.

Paper prepared by the above formula will, if carefully excluded from the light and air, by being placed between folds of blotting paper, keep good and sensitive for 24 hours.

The plan, however, which the Author has found best, is to prepare the paper early in the morning of the day on which it is to be used, and to develop the picture in the evening of the same day.

EXPOSURE IN THE CAMERA.

The time, as before stated, varies continually with every variation of circumstances, but from 3 to 10 minutes will be found the most usual range under ordinary conditions of light and subject. On removal from the camera, I generally prefer to see a slight trace of the picture, such as the outline of the landscape against the sky; this, when attentively observed, will be found a good criterion of the proper length of exposure to the luminous influence.

THE DEVELOPMENT OF THE PICTURE

Is performed by spreading the surface with the solution of gallic acid, by means of the glass rod, taking special care that the paper be evenly covered, and that no part be allowed to become dry. This treatment is continued until the whole of the details of the picture become apparent, but still of a light colour; at this point, a few drops of aceto-nitrate of silver are to be added, and spread over it as quickly as possible, in order to deepen the tone, and to give vigour to the dark portions of the picture. When the development has been carried sufficiently far—which may be judged of, as before directed, by carefully raising one corner of the paper, and viewing the impression by transmitted light—the picture is to be transferred to a pan of clean water, and thence to the

FIXING BATH,

Composed of 4 ounces of hypo-sulphite of soda to 1 pint of water, in which it is to soak for about ten minutes, until the whole of the yellow colour disappears, when removal to a vessel containing an abundance of water, will, after two hours' soaking, complete the operation of obtaining a negative by this process.

From the remarks made at the commencement of this paper, it will hardly be apparent what part the acetic acid plays in the

sensitive solution; but in order that the reader may be acquainted with the rationale of the process more fully, we propose to lay before him the following simple experiment:—

The reason for using the acetic acid in the sensitive solution, is to preserve the lights of the picture; its mode of action will be seen thus:—

Precipitate some sub-iodide of silver in two test tubes; let one of them be exposed to the light, and the other carefully excluded from it; that exposed will present a slightly altered aspect—it will have become of a light buff colour. If now we add to each of these precipitates a saturated solution of gallic acid, both will turn nearly black; that which has been exposed being the first to show the change, the difference being apparently only one of intensity. Such, however, is not the case, for on adding a quantity of glacial acetic acid to each of the tubes, that which had undergone the influence of light will remain unaltered; while that which has been carefully excluded from its action will become clear, and present as pure a surface of yellow iodide of silver as at first; clearly showing that the acetic acid has the power of dissolving the oxide of silver that is let down by the action of the gallic acid, while it fails to disturb the deposit caused by the action of the solar influence.

It will be seen from the above that we have illustrated precisely the conditions that obtain in the Calotype picture, the dark parts retaining their intensity, while the parts which have not been acted upon by the light are preserved in all their integrity by the clearing action of the acetic acid.

WAXING PAPER NEGATIVES.

Negative pictures taken by either of the foregoing processes are much improved in transparency and definition by being saturated with white wax; the best mode of accomplishing which is, to soak the picture in boiling water for a few minutes to remove all the size from the paper, and then, after thoroughly drying it, to lay the picture face downwards on to a piece of blotting paper, and to pass over its back a flat iron that has been heated, at the same time a piece of perfectly pure white wax is to be held in contact with and

made to follow the iron; the paper will by this means become impregnated with the wax, but on inspection it will be found that too large a quantity is on the surface; this is to be removed by placing the waxed picture between folds of perfectly clean blotting paper, and again passing a hot iron over the whole: by this operation the wax is again melted and the superfluous quantity absorbed by the super-imposed bibulous paper.

Pictures treated in this manner can be printed from with as much ease, and with almost as satisfactory results, as those taken on glass, the detail being brought out in a remarkable degree, the wax counteracting to a very great extent the unevenness of texture in the paper which militates so powerfully against the perfection of paper photographs.

THE WAXED PAPER PROCESS.

APPARATUS REQUIRED IN THE WAXED PAPER PROCESS.

Tin dish, for waxing paper.
 Argand lamp.
 Porcelain pans.
 Glass pan.
 Horn forceps, for taking paper from baths.
 Glass measures.
 Funnel.

SOLUTIONS REQUIRED FOR THE WAXED PAPER PROCESS.

Iodide of cadmium	640 grains.
Bromide of cadmium	160 do.
Pure iodine	6 do.
Distilled water	2 ounces.
Alcohol	2 do.
Skimmed milk	36 do.

Filter for use.

Nitrate of silver	400 grains.
Glacial acetic acid, absolutely pure	10 drachms.
Distilled water	10 ounces.
Iodide of potassium	4 grains.

Gallic acid	1 drachm.
Water	40 ounces.

Hypo-sulphite of soda	4 ounces.
Water	1 pint.

Much has from time to time been written on this branch of the subject, and many are the plans recommended for obtaining photographic proofs on waxed paper. The following process will, however, be found to possess the great advantage of simplicity, compared with the original one as described by Le Gray, to whom the art is indebted for the invention of this beautiful method of producing sun pictures.

The natural divisions of the process are—1st, waxing the paper; 2nd, iodizing the same; 3rd, rendering it sensitive; 4th, exposure to the image in the camera; 5th, development of the latent picture; 6th, fixing the proof.

1st. Waxing the paper. The paper most to be preferred for this process is that prepared by Canson frères. It is of an uniform texture and very thin, and is known at the shops as Canson's negative paper. A sheet of this is to be selected free from specks or blemishes of any sort, and treated in the manner following:—

Provide a flat tin dish about an inch deep (*Fig. 11*), and fit this into

Fig. 11.

an outer one that can contain water, which is to be kept at boiling heat by means of a lamp placed beneath; three or four

cakes of the best white wax being placed in the inner vessel and melted, a sheet of the selected paper is to be immersed in it, and allowed to remain in this

position until perfectly saturated with the wax. It may then be carefully raised by two of its corners and held over the vessel to drain, after which it is to be hung up to get cold: sheet after sheet may be treated in the same way. When a sufficient number is thus prepared, each sheet is to be placed between folds of blotting paper, and to have a hot iron passed over it; this will cause the wax to be re-melted, and the superfluous quantity absorbed by the blotting paper, thereby giving an uniform transparency to the paper. If all the superfluous wax be not absorbed, the surface of the paper will exhibit patches of undue brilliancy, owing to the outstanding of the wax. The paper, when properly prepared, should present a perfectly even and uniform surface, and the transparency ought to be without irregularity.

IODIZING THE WAXED PAPER.

This is accomplished by immersion in a bath prepared in the manner following:—

Dissolve 640 grains of iodide of cadmium, and 160 grains of bromide of cadmium, in two ounces of distilled water; next dissolve 6 grains of pure iodine in 2 ounces of alcohol of the specific gravity 840: when the iodide and bromide of cadmium are dissolved, add them to 36 ounces, by measure, of skimmed milk, and thoroughly agitate, now add the alcoholic solution of iodine, and again shake the mixture.

It will be noticed that the caseine of the milk is by this means precipitated in the form of white curd: the mixture is to be thrown on a filter and the clear liquid preserved for use; this forms the iodizing solution for waxed paper, and consists of the whey or serum of milk impregnated with iodizing materials.

The patience of the operator will be somewhat taxed during the filtration of the iodized serum, owing to the slow rate at which it leaves the funnel; the best way is to set it aside for some hours, and when it has ceased to pass through the filter the precipitate may, with advantage, be washed with distilled water, which after filtering may be added to the iodized serum; this will make up for the waste caused by the bulky precipitate of caseine.

In order to iodize the waxed paper pour a sufficient quantity of

the iodizing solution into a porcelain dish, and immerse the sheets in it one after another, taking great care that no air-bubbles are included between the surfaces of the paper and liquid; when a sufficient number have been immersed, they are to be allowed to soak for one hour, the whole mass of papers is then to be turned over in the liquid, in order to bring the sheet first immersed to the top; during the time of immersion the paper will have changed colour and will have assumed a purple tint, owing to the combination of the free iodine with the starch in the glaze of the paper. The sheets are now to be carefully removed from the bath, and hung up by the corners to dry.

The iodized paper when finished ought to be of a violet or purple tint, and should present rather a rough texture on the surface.

Should any drops form on the surface of the sheet of iodized paper while drying, it is an indication that some more alcohol must be added to the solution before a fresh quantity of paper is prepared. These spots are also apt to occur when the wax used in the preparation of the paper is contaminated with stearine or other fatty matter. The wax used should be perfectly pure, and should be obtained of some photographic house, as that usually considered pure by oilmen is not really so, and contains many impurities.

RENDERING THE PAPER SENSITIVE.

The sensitive bath is thus composed:

400 grains of crystallized nitrate of silver.

10 drachms of glacial acetic acid.

10 ounces of distilled water.

4 grains of iodide of potassium.

Filter a small quantity of this solution into a flat porcelain dish, as directed for iodizing, and float on to the surface a sheet of the iodized paper; allow it to rest for a few moments until the purple tinge is removed; then thoroughly immerse the sheet, and after waiting three minutes remove it by means of a pair of horn forceps

Fig. 12.

(*Fig. 12*) to a pan of distilled water for the space of five minutes, occasionally agitating during the immersion. The paper thus pre-

pared is to be placed between folds of bibulous paper, and finally hung up to dry.

If the above operations have been skilfully carried through, the paper will present an even coating of iodide of silver, and will keep sensitive for ten or twelve days at the least. I have used paper thus prepared after 15 days in cool weather. It should be preserved between leaves of clean blotting paper for use.

EXPOSURE IN THE CAMERA.

The time of exposure, as in all the other processes before described, must depend on various circumstances. With a 3-inch lens, and a stop of $\frac{1}{2}$ -inch diameter, and an ordinary landscape, in bright weather from 5 to 15 minutes will be found sufficient, but if the weather be very dull, 20 minutes will not overdo the picture; this will convey only an idea of the time required. The correct amount of exposure can alone be determined by experience.

DEVELOPMENT OF THE LATENT PICTURE

Make a solution of gallic acid in water, of the strength of

Gallic acid 1 drachm.

Water 1 quart.

Filter this into a porcelain pan, and float the paper on its removal from the dark slide of the camera, taking care to exclude all air bubbles. The development will soon commence, if the right time of exposure has been given. When nearly all the picture is brought out, which may be seen through the back of the sheet, remove it from the pan, and add to the gallic acid solution some aceto-nitrate of silver—the same as used for rendering the paper sensitive—in the proportion of $\frac{1}{2}$ a drachm of aceto-nitrate to 4 ounces of gallic acid solution; thoroughly mix, and immerse the partially developed proof; the details will soon begin to come out, and, at the same time, the dark parts of the picture will gather intensity; the degree of development may be judged of by holding the paper between the eye and the candle, or lamp, by the light of which we are operating. As in the Calotype process, we must guard against over-development, which will cause a deposit in the parts that ought to be transparent, thereby

rendering the shadows in the resulting positive thick and muddy, instead of sharp and bright.

It is necessary to thoroughly mix the aceto-nitrate with the gallic acid as directed above, otherwise the proof will become marbled all over to such an extent as to be useless as a negative. Various reasons have been assigned for this marbling by different operators, but I have found, by actual experiment, that it is caused by an imperfect admixture of the aceto-nitrate and the gallic acid.

The experiment was as follows:—

A waxed paper picture was partially developed in gallic acid alone; when all the details were apparent, it was removed and washed in distilled water; it was then cut in half. Half the gallic acid was poured into another pan, and some aceto-nitrate added to it and imperfectly mixed with it: into this pan one half of the partially developed proof was plunged. In a very few minutes the paper was marbled all over in a most distinct and unmistakable manner. The other half of the gallic acid was poured into a measure, and the aceto-nitrate added to it, and the mixture was well stirred with a glass rod; it was then turned into a clean dish, and the remaining half of the partially developed proof immersed in it, and in due course it came out a most splendid negative, perfectly free from marbling, and quite clean in every other respect.

A word or two on over and under-exposure of the paper in the camera:—It will be seen from the directions given under that head, that a great latitude is given, because the waxed paper process is essentially rather slow in its results. If the paper be under-exposed, the image will be a very long time before it makes its appearance, when under the influence of the gallic acid bath; if, on the contrary, it has been over-exposed, the picture will come out in a few minutes, and will finally assume a reddish cast or hue, which will greatly interfere with the beauty of the positive impression—the sky in a landscape will not present that opacity so essential to a successful proof, but will be patchy and uneven, showing some parts by transmitted light to be much lighter than others. The usual time of development of a picture is from half an hour to one and a half; but this is of little consequence, as several of them can be placed in

the gallic acid bath together, after the picture has made its appearance, and developed at one time; some little care is necessary however, in this part of the process, in order to prevent the staining that is so apt to occur. This may be obviated by occasionally turning the pictures in the bath, to remove any deposit that may have settled on their surfaces.

FIXING THE PROOF

Is effected by immersion of the paper in a solution of hypo-sulphite of soda, of the strength of—

Hypo-sulphite of soda	4 ounces.
Water	1 pint.

and allowing it to soak until all the yellow colour is dispelled from the light parts; this will generally be the case in about ten minutes or a quarter of an hour, after which it is to be removed to a pan and well washed in abundance of cold water for about two hours, and finally it is to be hung up to dry. When perfectly dry, place the picture between folds of blotting paper, and pass a hot iron over it in order to re-melt the wax, and restore the transparency which has been partially lost during the various manipulations. This will complete the process of obtaining a negative picture on waxed paper.

The Author was led to the consideration of the Waxed Paper Process, from the assurance that it possessed advantages that were particularly required by the tourist and the photographer in search of the picturesque; in commencing his experiments, however, many difficulties presented themselves, such as the preparation of the serum of milk, &c., for the iodizing solution, and also the fact that when the iodized paper was immersed in the bath of the aceto-nitrate of silver, in order to be rendered sensitive to light, if great care were not taken to hit the exact time of immersion, the nitrate of silver attacked the freshly-formed iodide of silver in the paper, and rendered it impossible to obtain a strong negative. Another difficulty occurred in the ordinary process, namely—during the development of the picture by immersion in the gallic acid, the back part of the paper presented a muddy appearance, which tended to obscure the lighter parts of the view.

In pictures taken by the ordinary Waxed Paper Process, it not unfrequently happens that the skies are not perfectly uniform and black, but present, when viewed by transmitted light, innumerable little pinholes as it were; and, also, the outlines of the objects of the view, instead of being perfectly sharp and clear, appear, when viewed under a magnifier, to be serrated and irregular.

The whole of these inconveniences and difficulties are surmounted in the process we have just described. In the first place, the serum is prepared and iodized at the same time by the iodide and bromide of cadmium; the solvent power of the bath for iodide of silver is taken away by its previous saturation with that salt; and the mudiness on the backs of the negatives is provided against and prevented by floating them until the picture is partially developed, instead of immersing them at once.

The sandy and gravelly skies that form so great a drawback to the Waxed Paper Process, as generally practised, are entirely removed by the use of iodide and bromide of cadmium, instead of iodide of potassium, this latter salt, by crystallizing in the texture of the paper, being the cause of the transparent pinholes before alluded to. For the same reason, the outlines of the objects in the picture are clear and bright; and, lastly, the use of the salts of cadmium renders this process particularly applicable in India and hot climates generally, the paper prepared as directed not being injuriously acted upon by moisture, as is the case where iodide of potassium is used.

For the information of those readers who may be about to practice this particular branch of photography, we would refer to an arrangement of camera particularly suited to open country work, with the paper processes, and with which the Author has worked most successfully.

The camera (*Fig. 14*) consists of a frame capable of receiving the ground focussing glass and the dark slide for the prepared papers. To this frame is hinged, at its lower part, the bottom board of the camera, which also is hinged so as to fold up more conveniently. The body of the camera is made of strong black cloth, perfectly impervious to light, and in the form of a truncated pyramid; the large end of it is fastened to the frame that contains the dark slide,

and the other is closed by the mahogany board that carries the lens. This board is furnished at its lower end with a pair of lifting hinges, which allow of the front being removed when the camera is to be folded up; a brass rod, secured by a screw extending from the frame at the back to the mahogany front carrying the lens, completes the arrangement. It will be seen that very little time need be occupied in fitting up and taking down this camera; also, the parts of the arrangement being all connected together, there is no danger of suddenly discovering on a journey that we have lost or mislaid any essential screw or fastening at the moment we wish to use it.

The diagrams represent a camera for pictures 11 in. by 9 in., drawn to the scale of one inch to the foot.

Fig. 13 represents the camera when folded for travelling, *Fig. 14* the camera in use. The weight of this camera and glass frame is only $4\frac{1}{2}$ lbs.

Fig. 14.

THE POSITIVE PAPER PROCESS.

APPARATUS REQUIRED FOR THE POSITIVE PAPER PROCESS.

Three porcelain pans (shallow).

One deep ditto, for washing.

Glass measure.

Pins.

Reversing or printing frame.

SOLUTIONS REQUIRED IN THE POSITIVE PAPER PROCESS.

Pure chloride of barium	$\frac{1}{2}$ ounce.
Distilled water	20 ounces. 1 pint

Nitrate of silver	$1\frac{1}{4}$ ounce.
Distilled water	10 ounces.
Glacial acetic acid	5 drops.

Hypo-sulphite of soda	1 lb.
Water, filtered	30 ounces.
Chloride of gold	15 grains.

PLAIN PAPER PROCESS.

PREPARATION OF THE PAPER.

The papers best adapted for this purpose are Hollingsworth's thin paper, or that made by Canson frères, and known as Canson's Positive. Having carefully selected a sheet free from specks or blemishes of any kind, prepare the following solution :—

Pure chloride of barium	$\frac{1}{2}$ ounce.
Distilled water	20 ounces.

This is to be filtered into one of the shallow pans and covered over with a sheet of cardboard or paper to keep out the dust, until the operator is quite ready to float the positive paper.

The sheet of positive paper being cut the required size, is to be held between the thumb and forefinger of each hand, and bent into the form of the letter **U**; the centre of the letter is then to be brought in contact with the solution in the pan, and the ends of the sheet gently lowered until the whole of the surface is in contact with the liquid. Care is required to prevent the formation of air bubbles, but a little attention and caution in manipulation will prevent their occurrence.

The paper being thus floated is to be allowed to remain on the liquid for three minutes, at the expiration of which time it is to be cautiously removed and hung up by one of its corners to dry.

It is almost needless to remark that this part of the process may be conducted in open daylight.

The paper thus salted may be preserved in a portfolio for an indefinite period, provided it be not subjected to the action of a damp atmosphere, and is ready at any time to be rendered sensitive in the manner following.

Make a solution as follows:—

Nitrate of silver	1½ ounce.
Distilled water	10 ounces.
Glacial acetic acid	5 drops.

This is to be carefully filtered into another shallow pan kept for the purpose, and a sheet of the salted paper prepared as directed is to be floated on to it, taking especial care that all air bubbles are excluded between the paper and liquid. Suffer the paper to remain on the solution undisturbed for three minutes, and carefully remove it and hang up by one of its corners to dry as before. When dry, the paper is fit to be placed in the reversing frame to be exposed to the solar agency.

THE REVERSING FRAME.

If we expose a piece of the paper as prepared above to the agency of light, it will in a very short time become blackened; but if any opaque object be placed upon it, the part immediately beneath that object will remain perfectly white. It is on this principle that the production of positive pictures depends. Thus we place a piece of the prepared paper with its sensitive side upwards on any convenient support, and bring the face of the negative in contact with it. If now we allow the light to shine through the negative, we shall find on inspecting the positive paper underneath that a very decided action has taken place over those parts corresponding with the light portions of the superposed negative.

Fig. 15.

The mode of accomplishing this end in practice is by means of a frame of wood (*Fig. 15*), in which is fixed a stout plate of glass: on this we place the negative, either glass or paper, face upwards—that is, turned away from the surface of the glass. The sensitive side of the positive paper is now brought in contact with the negative, and a board, lined with cloth or velvet, is placed over the whole; this in its turn is pressed down hard so as to bring the two in close contact by means of suitable screws and fastenings.

The back board in the reversing frame is hinged, which allows the operator to examine the state of forwardness of the picture by releasing one side at a time, and carefully separating the positive paper from the negative. The picture, after exposure for the proper time to the light, ought to be somewhat darker than the desired colour, to counteract the effect of the toning bath which takes part of the intensity from it.

THE POSITIVE TONING AND FIXING BATH

Is composed of—

Hypo sulphite of soda	1 lb.
Water (filtered rain)	30 ounces.
Chloride of gold	15 grains.

Dissolve the hyposulphite of soda in 28 ounces of water, then dissolve the chloride of gold in 2 ounces of water, and add it by degrees to the solution of hyposulphite, stirring all the time with a glass rod; this bath is ready for use in about 12 hours after it has been made.

The positive picture which has been over-printed, as directed above, is immersed in this bath, and is suffered to remain in it until the desired color is acquired. At the first immersion the beautiful

color of the sun-print will vanish and be replaced by a dull brown; but eventually the tone will change through various shades from a rich sepia to a black.

The action of the bath may be stopped in an instant at any point, the time of immersion determining the exact shade of color. In cases where the black tone is required, it is better to over-print the picture considerably, but where a neutral tint would be better adapted to the subject, the action of the light may with advantage be stopped at an earlier period.

The toning bath may be used for a considerable number of pictures, but when it ceases to impart a color to the prints treated with it without prolonged immersion, a little more solution of chloride of gold may be added with advantage.

The print having assumed its required tone under the action of the toning bath, is to be removed to a deep dish of water and thoroughly agitated in it for a few minutes; the water is then to be changed four or five times in succession, this agitation being repeated between each change; finally, the print is to be immersed in a large pan of water and allowed to soak for six or eight hours at least in order to remove every trace of hyposulphite of soda, which would eventually cause it to fade if present even in the smallest quantity. Suspension in a warm place to dry, and subsequent ironing or hot-pressing, will complete the process of taking positive pictures on plain paper.

There is, however, another method, or rather a modification of the last, by which the paper is coated with a layer of albumen, in which the chloride of barium has been dissolved. In this mode we obtain pictures of exquisite minuteness of detail, the surface on which the image is formed being free from those irregularities appertaining to plain paper.

ALBUMENIZED POSITIVE PAPER PROCESS.

The subjoined method of preparing the albumenized paper will be found both certain and simple, and will give exceedingly fine results. The proportion of albumen is comparatively small, but it will be found quite sufficient to give the required surface without rendering the paper too glossy.

Take the whites of six eggs, throw them into a large bottle, say a Winchester quart, add thereto 12 ounces of distilled water, in which has been dissolved 270 grains of chloride of barium, thoroughly agitate the mixture until the froth occasioned fills the bottle, then allow it to stand for seven or eight hours, and finally filter the salted albumen through two thicknesses of bibulous paper into a perfectly clean bottle for use.

To albumenize the paper—

Pour some of the salted albumen into a shallow dish, and having carefully skimmed the surface by means of a piece of card, float a sheet of the selected paper on the surface, as directed, while treating of plain paper, (page 62). Allow the sheet to remain in contact with the albumen one minute and a half, then carefully raise it and hang it up by one of its corners to dry. When dry, the paper thus albumenized must be placed in a portfolio free from damp, where it may be kept for an indefinite time.

It is worthy of remark, that if we leave the paper on the albumen for a longer time than indicated above, we do not obtain so good a result; the albumen appears to soak into the paper and the gloss on the surface is much diminished.

It will be found a means of preventing streaks on the albumenized paper if the salted albumen in the dish be occasionally skimmed with the piece of card before mentioned. This removes dust, bubbles, and a peculiar web-like structure that forms on the surface of the albumen when it has been exposed to the action of the atmosphere for some time in an open dish.

Should the surface of the paper not present sufficient gloss to meet the wishes of the operator, the proportion of water may be lessened in making the salted albumen, still preserving the proper proportion to the ounce of chloride of barium, namely, 15 grains of crystal to the ounce of liquid.

To render the albumenized paper as prepared above sensitive, and to fit it for the reversing frame, it is to be floated, albumen side downwards, on a bath composed in the following manner:—

Nitrate of silver	1½ ounces.
Distilled water	10 ounces.
Glacial acetic acid	5 drops.

Filter carefully into a shallow pan kept for the purpose.

The sheet is to be allowed to remain in contact with the above for the space of three minutes; it is then to be removed as quickly as possible and to be hung up by one of its corners to dry. The drying may be facilitated by placing a fragment of the bibulous paper in contact with the lower corner. When dry, the paper is fit for the reversing frame.

The printing, toning, and fixing, are performed in precisely the same manner as directed for plain paper, (pages 64-5) the only difference being that the albumenized paper requires rather a longer immersion in the toning bath before the dark tones are acquired, and also a greater amount of washing, in order to remove the hyposulphite of soda, than is necessary for plain paper.

Pictures taken by the above process, for sharpness of outline, depth and transparency of shadow, and delicacy of detail, are not to be surpassed, and for certain subjects are immeasurably superior to those produced by the ordinary method.

We have recommended a very dilute solution of albumen for the preparation of the paper, because we consider that it fulfils all the conditions necessary to produce a perfect picture without the vulgar glare so objectionable in pictures printed on highly albumenized paper. There is one exception we would take, however, to this remark—namely, stereoscopic pictures: these, from being seen under a lens, are improved by being printed on highly albumenized paper, as it prevents the texture of the material from being very apparent; but even here we must exercise taste and judgment so as not to overdo the affair.

THE METHOD OF TAKING STEREOSCOPIC PICTURES.

Before entering upon the details of the plan by which stereoscopic pictures are produced, it may not be out of place to endeavour to put the reader in possession of the theoretical principles on which the stereoscope depends for its action. Every one is aware that the human subject possesses two eyes, but it is not so clear to most

people what use is made of them as a means of informing the mind of the nature and condition of objects which are rendered visible through their agency. If we stand in a room, and look through a window at objects on the opposite side of the street, we can pronounce of a certainty that the horse there waiting patiently for its rider is possessed of three dimensions—namely, length, breadth, and thickness; in fact, that it is, as far as vision is concerned, a solid body: now by what means is this conviction formed in our minds? We say, by the impression formed on the brain, through the optic nerves, of two different images of the object, one formed on the retina of the right eye, the other on that of the left; for while still looking at the same object, if we close the right eye, and notice what part of the animal is intersected by a bar of the window, and then close the left and open the right, we shall find in the second case the same bar intersects quite a different part of the horse, clearly showing that on the retina of each eye we have formed quite a distinct image of object at which we are looking; it is the combination of these two images, through the agency of the optic nerves, that gives rise to our notions of solidity in objects presented to our notice.

Bearing this in mind, then, it is not difficult to conceive how it may be possible so to take, by means of the camera, two dissimilar pictures, and then, through the medium of an instrument called the stereoscope, so to combine these pictures as to render to the mind the idea of solidity of the object viewed. These conditions have been realized, and with the aid of photography, we are enabled to bring to our homes views of distant regions and works of art, that convey most exact ideas of locality and of the peculiar features of the subject under consideration.

The stereoscope, as an optical instrument, exists in two forms—namely, the reflecting stereoscope, as originally designed by Professor Wheatstone, and the lenticular stereoscope of Sir David Brewster; each of these instruments possesses advantages peculiar to itself, the reflecting one being suited to the exhibition of views of any size, while the lenticular stereoscope is only adapted to pictures of small dimensions.

The reflecting stereoscope (*Fig. 16*), consists essentially of two

*Fig. 16.*

mirrors, set at an angle of 90° to each other; opposite these mirrors, suitably supported, are placed the pictures to be viewed; the frames that support the pictures admit of every adjustment, so that the two images as seen by the eyes placed opposite the mirrors may be made to coincide.

*Fig. 17.*

The lenticular stereoscope of Sir David Brewster (*Fig. 17*) consists of a box, shaped as in the figure, at the broad end of which the pictures are placed; immediately opposite these pictures are situated the eye-pieces that contain two semi-lenses, that is, lenticular prisms, so placed that their

centres are coincident with the pupils of the eyes; the action of these semi-lenses is to cause the images viewed through them to overlap each other, so that instead of two pictures seen side by side, we have one picture visible in the apparent centre of the instrument, giving the true stereoscopic effect.

Stereoscopic pictures may be taken by an ordinary camera, or by cameras specially adapted for that purpose; for large pictures the ordinary landscape camera can be used with advantage; the mode of procedure is as follows: Place the camera in the true position for

taking the views, and having previously made a cross in pencil on the ground focussing-glass so as to intersect the centre of the picture

thus, note, when focussing, the particular object or part of an object that falls on the intersection of the lines; then take the picture. When the exposure has been sufficient move the camera and stand bodily, as nearly parallel to the plane of the view as possible through the space of four feet, and then focus for the second picture, taking care that the image of the same object or part of an object falls on the point of intersection of the lines on the focussing glass; the picture may then be taken, and when the negatives thus produced are printed from, and the results placed on their respective sides of the reflecting stereoscope, a most magical effect is produced, for on looking into the mirrors with both eyes, and adjusting the pictures so as to coincide, the views will appear in perfect relief; every part will show itself in its proper position, and the effect of solidity will be given to every object in the composition.

For small views used in the lenticular stereoscope, and for portraits, we use either of the cameras represented below. *Fig. 18* represents

Fig. 18.

a stereoscopic camera of the most simple form: it consists of a long camera box with a dark slide to hold the plate on which the two pictures are to be taken; the front which carries the lens is so made as to slide from side to side; the method of using the instrument is very simple—the camera is placed immediately

opposite the object to be taken, and the front carrying the lens, is moved to one side; the object being focussed, the prepared plate is then placed in the dark slide and substituted for the ground focussing-glass. Now uncap the lens and expose the one half of the plate, replace the cap, and then shift the lens to the other side, and expose the other half for the same length of time. On development, the pictures, if properly exposed, will come out of the same intensity, and of uniform appearance. The negative thus produced can be

printed from in the usual way, and the resulting pictures being mounted on card, can be viewed in the lenticular stereoscope, where all the peculiarities due to the manner in which they have been taken will manifest themselves. There is one point to which we must draw attention in mounting the pictures taken with this instrument, namely, that they must be placed on the mounting card in the reverse position to that which they occupy when on the glass—that is to say, the left hand one on the glass must occupy the right hand place on the cardboard mount—otherwise, it is obvious from what has been before explained, that the true stereoscopic effect cannot be obtained.

Fig. 19.

Fig. 19 represents a camera on the same principle, but fitted with two lenses of precisely the same focus; the caps of these lenses are so connected together that they may be removed simultaneously, so that by this arrangement it is possible

to take both pictures at the same instant; this will be found particularly convenient when the object is likely to move, as in the case of a portrait, where it is almost impossible for the sitter to keep in one position for any great length of time.

The same remark holds good in the use of this camera as with the last with regard to mounting of the finished pictures—in order to obtain the true stereoscopic effect, we have to reverse the position of the pictures, as before explained.

Fig. 20 is a drawing of another form of stereoscopic camera, and is adapted for taking views as well as portraits; it consists of an ordinary portrait camera, mounted on a board, which is furnished at its bottom with bars of wood; these bars are so fitted as to admit of adjustment, in order that the camera may be moved from right to left, and *vice versa*, either on the same plane, or in the circumference of a circle; the back of the camera is so constructed, that the portion of it that holds the glass plate can slide from side to side; this is accomplished by means of a silk cord and spring attached to it, and

*Fig. 20.*

also to an immovable pillar on the base board of the apparatus. When a picture is to be taken, the sliding back is to be removed, and replaced by the ground focussing-glass; the camera is then moved to the left as far as it will go. The focus being taken, and the position of any object marked on the screen, the camera is to be moved in the opposite direction until it comes to a stop; if the object before noted occupies the same spot on the ground glass, we may consider the adjustment perfect; but if not, we must alter the parallelism of the bars by means of the adjusting screws, and make a second trial.

When the two images occupy the same relative positions on the ground glass, we place the prepared plate in its proper position and draw the camera to the left, the right-hand side of the plate being opposite the lens; uncap the lens and expose the plate, then replace the cap and move the camera to the right hand; this motion will cause the slide that holds the plate to present its left side to the opening before the lens; again uncap the lens and take the second picture. The negative thus produced may be printed from, and the resulting positives mounted in the same relative positions as they occupied on the glass plate.

We may state here that any of the processes before described can be carried out with these cameras, but owing to the small size of the pictures perhaps the collodion or albumen processes are to be recommended in preference to those on paper.

ON COLORING POSITIVES ON GLASS.

Under this head we purpose to give a few hints and particulars with regard to the tinting of positive pictures that we hope will be found useful to the amateur. The application of the color to the photograph is a matter of some nicety, although a very simple one, and as much more of the success depends on the artistic excellence of the picture than on the amount and variety of color lavished in its production; a few words on the arrangement of the operating room may not be out of place.

In the first place, then, the light should be so under control by means of blinds that it may fall on the sitter in an oblique direction, and in such a manner that the shadows under the brows and other prominences of the face may be well defined, though not harsh, and the sitter should be so placed that one side of the face may be in comparative shadow. A northern aspect is the best for an operating room, as that is free from the glare attendant on one with a southerly direction.

Strong contrasts of light and shade are specially to be avoided, and the operator will find great assistance to artistic excellence in the use of white screens, which are, by a judicious disposition, extremely useful in lessening the depths of shadows and producing reflex lights so conducive to pleasing effect in a picture. It is astonishing what an immense difference there exists between a picture taken in the broad daylight where the light is coming from every point and one taken under circumstances where attention has been paid to the direction and amount of light that has fallen on the sitter; in the former case the picture will appear flat and unmeaning, and in the latter we shall observe that peculiar stereoscopic effect which characterizes a good photograph.

Photography, as applied to portraiture, has in some quarters got into disrepute from the miserable caricatures presented to us by the inexperienced operator; the eyes present a fishy and dead expression, and the face is as flat as a full moon. These defects can, however, be obviated by a little attention. In the first place, the eyes of the sitter should be protected from too great a glare of light

and should be directed to some object in the operating room of a sombre color; by this means we shall obtain a fine open pupil and get rid of that peculiar glassy appearance so detrimental to a successful likeness. In the next place we may obviate much of the flatness by proper attention to the time of exposure, as I explained at page while treating of exposure of positives in the camera. It is impossible for the high lights to become whiter than white, and by continuing the exposure, in order to "get out" the dark drapery, we are apt to overdo the face and light parts of the picture.

The back-ground should be dark, not white, as nothing looks so monstrous as a black image mounted, as it were, on a white ground; it puts one in mind of the monstrosities formerly perpetrated in black paper and stuck on cards, and only to be met with at country fairs and such places.

The color that is best suited for a back-ground is dark buff, and the material should be canvas painted in distemper color; the brush marks need not be carefully erased, as a certain roughness of surface adds force and breadth to the effect of such a back-ground. On no account let the operator indulge in the conventional pillar and curtain, the landscape and cottage with the smoke gracefully curling from the chimney; these are out of date and vulgar. The same remark may equally be applied to the everlasting vase of flowers and dyed grass always to be found on the tables of some operators.

The furniture of the operating room should be of the most chaste description, and the chairs, couches, &c., should be selected with an eye to the elegance of form rather than to meretricious adornments of fine carving and French polish.

The best covering for the floor of an operating room is some light colored oil-cloth, as plain in design as possible; this tends to give a softness to the shadows, by reflecting light upwards.

The above remarks, if carefully attended to, will insure pictures that are worth coloring and that will well repay the operator for the trouble of their productions.

The coloring of positive photographs is accomplished by means of colors in extremely fine powder, applied with camels' hair brushes.

The colors mostly employed are—

White	Flesh color, three shades
Green, of three shades	Carmine
Scarlet	Lips
Pink	Lavender
Claret	Blue, Prussian
Orange	Ultramarine
Rose	Black
Yellow, three shades	Gold and silver shells.

The choice of colors must, of course, depend on the taste of the artist; the mode of applying them is as follows:—

The plate being quite dry, we take up a small portion of color on the point of one of the fine brushes, and with a light hand apply it to the part required to be tinted, giving the brush a circular motion. We must not apply too much color, but use it as sparingly as possible. This part of the process may be considered as the first wash in landscape painting. Having gone over the whole of the picture we remove the superfluous color by means of the India-rubber bottle.

The plate is now to be varnished as before described, and, when quite hard, we may begin to work in the complexion tints, the color of the eyes, and with the white color go over those parts which are over-done, and which have lost their brilliancy from over-development.

The gold ornaments, chain, studs, &c., may now be touched in, exercising all the time great care that too much color is never applied at one time, otherwise, instead of a beautifully soft finished picture, we shall have as a result one that is patchy and in every way unsatisfactory.

The back-ground of the picture is tinted in the same manner, only using a larger brush. The fleecy clouds that are considered by some as an advantage, are best put in with a stump; this must be done with a very light hand, and the edges may be softened off with a large long-haired brush.

As a matter of practice, it will be found better to fill in all the lighter tints first, and gradually proceed with the darker ones; the operator will, by this means, be better able to judge of the effect he is producing.

The picture will not require varnishing a second time if the colors have been skilfully applied. If by accident they should present a dull appearance, a coating of gelatine, of the strength of two grains to the ounce of water, and applied hot, may be with advantage poured over the picture.

THE DRY COLLODION PROCESS.

The advantages of a certain and simple dry collodion process are so obvious to those who have practised photography in the open air, that the subject needs little introduction. I would, however, mention a few particulars connected with the process for the information of those who have not yet practised it; and, at the same time, would refer them for detailed particulars of manipulation to the pamphlet by the Author on the subject.*

Plates prepared by this process will keep sensitive for an indefinite period, and can be developed at any time without regard to the date of exposure. This, it will be seen, is of immense advantage to the tourist, as he can delay the development of the whole of his plates until his return.

To those photographers whose inclination or want of leisure will not admit of their carrying through the first preparation of the plate, these dry plates will be found invaluable, enabling their whole energy to be directed to the more careful selection of subject.

The plates being dry, there is no danger of dust settling on their surface. This point will be appreciated by every photographer.

The development of the picture can be conducted in any room where the light can be excluded, as the process is simple and clean, one dish and a levelling stand being the only requisites in point of apparatus.

To officers, engineers, and architects, these dry plates offer a desideratum of no small value, as they are *always ready for use*, occupy very little room in travelling, and can be used under circumstances which would preclude the adoption of any process that had to be carried out on the spot.

* The Dry Collodion Process, by CHARLES A. LONG. BLAND & Co., 153, Fleet Street, London.

In concluding the description of the various photographic processes on glass and paper, let me once more urge the necessity of attention to minute particulars in manipulation, and, above all, that cleanliness should characterize our operations in the highest degree. Without this feature no one can ever hope to attain proficiency in any department of this beautiful and interesting art; but, on the contrary, the careless operator will meet with nothing but failures as a reward for his negligence on this head.

THE END.

TENT FOR WORKING COLLODION IN THE OPEN AIR.

REPTILES PRICE LIST

Reptiles are the most interesting and valuable of the animal kingdom. They are found in all parts of the world, and are especially numerous in the tropics. The most common reptiles are the snakes, lizards, and turtles. The snakes are the most dangerous, but also the most beautiful. The lizards are the most numerous, and the turtles are the most valuable. The price of reptiles varies greatly, depending on the species and the quality of the specimen. The following is a list of the prices of some of the most common reptiles.

PHOTOGRAPHY;

Photography is the art of creating a permanent image of a scene or object. It is one of the most popular and useful of the arts. The first photograph was made in 1826, and since that time it has become one of the most important means of communication. The most common types of photography are the portrait, the landscape, and the scientific. The portrait is the most popular, and the landscape is the most useful. The scientific is the most valuable. The price of photography varies greatly, depending on the type of photograph and the quality of the work. The following is a list of the prices of some of the most common types of photography.
